A COMPREHENSIVE TREATISE ON INORGANIC AND THEORETICAL CHEMISTRY

VOLUME XI

Te, Cr, Mo, W

BY THE SAME AUTHOR

ELEMENTARY INORGANIC CHEMISTRY
With 129 Illustrations. Large crown 8vo, 3*s*. 6*d*.

INTERMEDIATE INORGANIC CHEMISTRY.
With 205 Illustrations. Large crown 8vo, 7*s*. 6*d*.

MODERN INORGANIC CHEMISTRY.
With 369 Illustrations. Crown 8vo, 12*s*. 6*d*. net.

HIGHER MATHEMATICS FOR STUDENTS OF CHEMISTRY AND PHYSICS. With Special Reference to Practical Work.
With 189 Diagrams. 8vo, 21*s*. net.

A COMPREHENSIVE TREATISE ON INORGANIC AND THEORETICAL CHEMISTRY.
8vo, £3 3*s*. net each volume.

Vol. I. H, O.
With 274 Diagrams.

Vol. II. F, Cl, Br, I, Li, Na, K, Rb, Cs.
With 170 Diagrams.

Vol. III. Cu, Ag, Au, Ca, Sr, Ba.
With 158 Diagrams.

Vol. IV. Ra and Ac Families, Be, Mg, Zn, Cd, Hg.
With 232 Diagrams.

Vol. V. B, Al, Ga, In, Tl, Sc, Ce, and Rare Earth Metals, C (Part I)
With 206 Diagrams.

Vol. VI. C (Part II), Si, Silicates.
With 221 Diagrams.

Vol. VII. Ti, Zr, Hf, Th, Ge, Sn, Pb, Inert Gases.
With 255 Diagrams.

Vol. VIII. N, P.
With 156 Diagrams.

Vol. IX. As, Sb, Bi, V, Cb, Ta.
With 161 Diagrams.

Vol. X. S, Se.
With 217 Diagrams.

PREFACE

I am very greatly obliged to my friends and colleagues Messrs. F. H. Clews, M.Sc., A.I.C., A. T. Green, F.Inst.P., A.I.C., A. Scott, M.A., D.Sc., and L. S. Theobald, B.Sc., A.R.C.Sc., for kindly reading the proofs of previous volumes, and the present volume.

CONTENTS

CHAPTER LIX

TELLURIUM

§ 1. The History and Occurrence of Tellurium (1); § 2. The Extraction of Tellurium (4); § 3. The Physical Properties of Tellurium (11); § 4. The Chemical Reactions of Tellurium (25); § 5. The Atomic Weight and Valency of Tellurium (32); § 6. Hydrogen Telluride (36); § 7. The Tellurides (40); § 8. Tellurium Monoxide and Dioxide (70); § 9. The Tellurites (77); § 10. Tellurium Trioxide and the Telluric Acids (83); § 11. The Tellurates (88); § 12. Tellurium Halides (98); § 13. The Oxyhalides of Tellurium (108); § 14. Tellurium Sulphides (110); § 15. Tellurium Oxysulphides and Sulphates (116); § 16. Tellurium Nitrates (119); § 17. Tellurium Phosphates (120).

CHAPTER LX

CHROMIUM

§ 1. The History and Occurrence of Chromium (122); § 2. The Extraction of Chromium as Chromic Oxide or Chromate (129); § 3. The Preparation of Chromium (133); § 4. The Physical Properties of Chromium (142); § 5. The Chemical Properties of Chromium (160); § 6. The Atomic Weight and Valency of Chromium (167); § 7. The Alloys of Chromium—Chromides (170); § 8. The Lower Chromium Oxides (174); § 9. Chromic Oxide (176); § 10. Hydrated Chromium Oxides—Chromium Hydroxide (185); § 11. Chromites (196); § 12. Intermediate Chromium Oxides (206); § 13. Chromium Trioxide, and Chromic Acid (211); § 14. The Chemical Properties of Chromium Trioxide (229); § 15. The Chromates. Monochromates (240); § 16. The Dichromates (323); § 17. The Trichromates (349); § 18. The Tetrachromates (351); § 19. Perchromic Acid and the Perchromates (353); § 20. Chromium Fluorides (361); § 21. Chromium Oxyfluorides (364); § 22. Chromium Chlorides (366); § 23. The Chromium Oxychlorides (390); § 24. The Chromium Ammines (400); § 25. The Complex Salts of Chromic Chloride (410); § 26. Chromium Bromides and Oxybromides (421); § 27. Chromium Iodides and Oxyiodides (427); § 28. Chromium Sulphides (429); § 29. Chromium Sulphates (434); § 30. The Complex Salts of Chromic Sulphates (452); § 31. Chromium Carbonates (471); § 32. Chromium Nitrates (473); § 33. Chromium Phosphates (479).

CHAPTER LXI

MOLYBDENUM

§ 1. History of Molybdenum (484); § 2. The Occurrence of Molybdenum (486); § 3. The Extraction of Molybdenum (492); § 4. The Physical Properties of Molybdenum (499); § 5. The Chemical Properties of Molybdenum (512); § 6. The Atomic Weight and Valency of Molybdenum (520); § 7. Alloys and Intermetallic Compounds of

Molybdenum (522); § 8. Molybdenum and Molybdic Oxides (525); § 9. Intermediate Oxides—MoO_2 to MoO_3 (526); § 10. Molybdenum Trioxide and its Hydrates (535); § 11. The Monomolybdates—Normal Molybdates (551); § 12. The Di-, Para-, and Tri-Molybdates (580); § 13. The Tetra-, Penta-, Hexa- and Hepta-Molybdates (591); § 14. The Octa-, Ennea-, and Deca-Molybdates (595); § 15. The Dodeca-, and Higher Molybdates (599); § 16. Permolybdic Acid and Permolybdates (605); § 17. Molybdenum Fluorides (609); § 18. Molybdenum Oxyfluorides (610); § 19. Molybdenum Chlorides (616); § 20. Molybdenum Oxychlorides (627); § 21. Molybdenum Bromides and Oxybromides (634); 22. Molybdenum Iodides, and Mixed Halides (639); § 23. Molybdenum Sulphides (640); § 24. Sulphomolybdates and Oxysulphomolybdates (650); § 25. Molybdenum Sulphates (656); § 26. Molybdenum Carbonates and Nitrates (659); § 27. Molybdenum Phosphates, and Phosphato- or Phospho-Molybdic Acids (659).

CHAPTER LXII

TUNGSTEN

§ 1. The History of Tungsten (673); § 2. The Occurrence of Tungsten (675); § 3. The Extraction of Tungsten Trioxide (682); § 4. The Preparation of Tungsten (689); § 5. The Physical Properties of Tungsten (699); § 6. The Chemical Properties of Tungsten (729); § 7. The Atomic Weight and Valency of Tungsten (738); § 8. Alloys and Intermetallic Compounds of Tungsten (741); § 9. The Lower and Intermediate Oxides of Tungsten (745); § 10. Tungsten Trioxide (753); § 11. The Hydrates of Tungsten Trioxide—The Tungstic Acids (762); § 12. The Monotungstates—Normal Tungstates (773); § 13. The Ditungstates and Tritungstates (809); § 14. The Paratungstates (812); § 15. The Metatungstates, and Tetratungstates (821); § 16. The Penta- and Higher Tungstates (828); § 17. The Pertungstic Acids and the Pertungstates (833); § 18. Tungsten Fluorides and Oxyfluorides (837); § 19. The Tungsten Chlorides (840); § 20. The Tungsten Oxychlorides (848); § 21. Tungsten Bromides and Oxybromides (853); § 22. Tungsten Iodides and Oxyiodides (855); § 23. The Tungsten Sulphides (856); § 24. The Tungsten Oxysulphides and Sulphates (860); § 25. Tungsten Carbonates and Nitrates (861); § 26. Phosphotungstic Acids—Phosphatotungstic Acids and their Salts (862).

INDEX 875

ABBREVIATIONS

aq. = aqueous
atm. = atmospheric or atmosphere(s)
at. vol. = atomic volume(s)
at. wt. = atomic weight(s)
T° or $^\circ K$ = absolute degrees of temperature
b.p. = boiling point(s)
θ° = centigrade degrees of temperature
coeff. = coefficient
conc. = concentrated or concentration
dil. = dilute
eq. = equivalent(s)
f.p. = freezing point(s)
m.p. = melting point(s)
$\text{mol(s)} = \begin{cases}\text{gram-molecule(s)}\\ \text{gram-molecular}\end{cases}$
$\text{mol(s).} = \begin{cases}\text{molecule(s)}\\ \text{molecular}\end{cases}$
mol. ht. = molecular heat(s)
mol. vol. = molecular volume(s)
mol. wt. = molecular weight(s)
press. = pressure(s)
sat. = saturated
soln. = solution(s)
sp. gr. = specific gravity (gravities)
sp. ht. = specific heat(s)
sp. vol. = specific volume(s)
temp. = temperature(s)
vap. = vapour

In the **cross references** the first number in clarendon type is the number of the volume; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus **5**. 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances A, B, and C, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle, ternary mixtures. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the

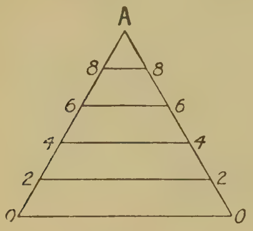

FIG. 1.

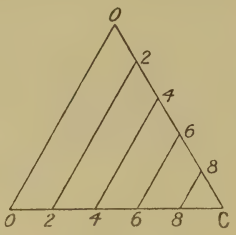

FIG. 2.

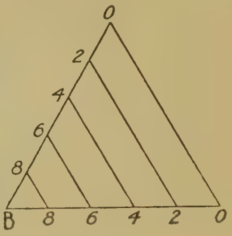

FIG. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

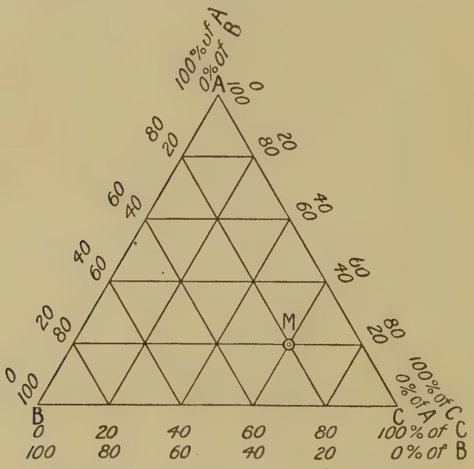

FIG. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER LIX

TELLURIUM

§ 1. The History and Occurrence of Tellurium

Up to near the end of the eighteenth century, the peculiar mineral known as *white gold-ore* or *grey gold-ore*, occurring in the sandstone near Zalathna, Transylvania, appears to have been considered by chemists and mineralogists as a kind of alloy of antimony and bismuth. One variety of the mineral was called *Gelberz, Schrifterz, Blättererz,* or *blätterige Graugolderz* by G. A. Scopoli;[1] and *or gris lamelleux* by I. Eques a Born. Later, it became the *Nagyager Erz* of A. G. Werner; the *Blattertellur* of J. F. L. Hausmann; and the *nagyagite* of W. Haidinger. Another variety, *Weissgolderz,* was called *or blanc d'Offenbanya,* or *or graphique,* or *aurum graphicum,* by I. Eques a Born; *prismatische Weissgolderz* by J. E. von Fichtel; and *aurum bismuticum* by J. G. Schmeisser. The *Weissgolderz* was afterwards called *sylvane graphique* by A. J. M. Brochant; *Schriftellur* by J. F. L. Hausmann; *Schrifterz* by J. Esmark; *sylvane* by F. S. Beudant; *sylvanite* by L. A. Necker; and *aurotellurite* by J. D. Dana.

C. A. Gerrard's analysis gave: 76 per cent. of sulphur and bismuth, 18 per cent. of gold, and 6 per cent. of silver; while A. von Ruprecht's analysis gave: gold, 11·6; silver, 2·33; lead oxide, 25; iron oxide, 16·66; arsenic oxide, 1·00; antimony oxide, 2·08; sulphur, 41·66 per cent.

In 1782, F. J. Müller von Reichenstein[2] showed that the *Weissgolderz* gave no indication of the presence of either antimony or bismuth, and he suspected that it contained a new metal, which he called *metallum problematicum* or *aurum paradoxum.* T. Bergman received a sample of the mineral, and examined it by the blow-pipe. He said that the metal is of a different nature from antimony, but he did not venture to give a decided opinion; although, according to P. Diergart, T. Bergman concluded that F. J. Müller von Reichenstein had discovered a new element. About 1789, P. Kitaibel also suspected the presence of a new element; and, a few years later, M. H. Klaproth extracted the unknown metal and observed a number of its properties, from which he concluded that the mineral contains a peculiar, distinct metal essentially different from every other metallic substance hitherto known; and he added that since these properties had previously been described in the crude mineral, it is to F. J. Müller von Reichenstein that the merit belongs of having first suspected in Weissgolderz a new and distinct metal, and of having demonstrated its probable existence. This was verified by J. F. Gmelin. M. Tihavsky tried to show that tellurium and antimony are the same; but the attempt was abortive.

Tellurium occurs in only a few places and in small quantities; it is less abundantly distributed than any other element of the sulphur family. It rarely occurs in the elemental state, and it is present only in tellurides and in a few oxidized ores. According to F. W. Clarke and H. S. Washington,[3] the igneous rocks on the earth's crust contain 8×10^{-2} per cent. of sulphur, $n\times10^{-8}$ per cent. of selenium, and $n\times10^{-9}$ per cent. of tellurium; and tellurium is about as abundant as gold. J. H. L. Vogt gave for sulphur 6×10^{-2}, selenium $n\times10^{-9}$, and tellurium $n\times10^{-10}$ per cent. W. Vernadsky gave $0{\cdot}0_56$ for the percentage amount, and $0{\cdot}0_65$ for the atomic proportion. H. A. Rowland[4] failed to detect the lines of tellurium in the solar spectrum ; and the subject was discussed by F. E. Baxendall. According to C. E. St. John, it is yet uncertain whether or not tellurium lines occur in the solar spectrum.

The occurrence of native tellurium at Nagyag, Transylvania, was discussed by V. R. von Zepharovich ;[5] at Oravicza, Transylvania, by B. von Cotta ; in Ruda, Erzgebirge, by F. Berwerth; in the vicinity of Zalathna, by M. H. Klaproth, W. Petz, J. Loczka, V. R. von Zepharovich, L. Tokody, G. Rose, A. Brezina, H. von Foullon, and G. Benkö ; in Asia Minor, by G. Cesaro ; in Colorado, by W. P. Headden, G. Rolland, B. Silliman, F. A. Genth, G. vom Rath ; in California, by D. L. Mathewson, G. Kustel, and F. A. Genth ; in Chile, by E. Bertrand ; in New South Wales, by A. Liversidge; in Western Australia, by R. W. E. MacIvor, M. Maryansky, and A. Frenzel ; and in the Transvaal, by A. Frenzel. The following are analyses of some native tellurium selected from these reports :

	Te	Se	S	Au	Ag	Fe	Gangue
Zalathna . . .	80·39	0·33	9·26	0·33	—	8·55	1·54
Zalathna . . .	97·92	trace	—	0·15	—	0·53	1·62 (Cu)
Magnolia (Colorado) .	96·91	—	—	0·60	0·07	—	2·42
Ballerat (Colorado) .	93·64	—	—	2·18	1·15	0·18	2·85
John Jay (Colorado) .	97·94	—	—	1·04	0·20	0·89	0·32 (Zn)
Gunnison (Colorado) .	99·45	0·40	—	—	—	0·11	—
West Australia . .	96·935	—	—	2·399	—	—	—

Tellurium occurs combined with gold, silver, bismuth, and many other metals. It is rather a nuisance in certain auriferous districts where the gold and silver ores are unfit for amalgamation, etc., because the telluride ores do not give up their gold to mercury, to cyanide, or to chlorine ; the ores also concentrate badly ; they are difficult to roast on account of their low m.p. and gold is lost during the removal of the tellurium. The telluride ores are smelted either with lead or copper ores which act as a flux. Large amounts of tellurium enter the copper matte. The mattes are then bessemerized, and the copper refined by electrolysis. The copper contains not far from 0·04 per cent. of tellurium. The slimes contain most of the tellurium, antimony, cæsium, and bismuth together with silver and gold. The chief tellurium minerals are the tellurides ; and the oxidized minerals are represented by tellurous acid, the tellurites and the tellurates. The **tellurides** include *tellurium bismuth glance*, Bi_2Te_3 ; *tetradymite*, Bi_2Te_2S ; *wehrlite*, Bi_7Te_7Ag ; and *pilasonite*, Bi_3Te_2—as well as the non-homogeneous *oruetite*, $Bi_2Te_3.Bi_2S_3$. There are also *joseite*, Bi_3TeS ; *grünlingite*, Bi_4S_3Te ; *rickardite*, Cu_4Te_3 ; *altaite*, PbTe ; *melonite*, Ni_2Te_3 ; *coloradoite*, HgTe ; *stützite*, Ag_4Te(monoclinic) ; *hessite*, Ag_2Te(cubic) ; *empressite*, AgTe ; *petzite*, $(Ag,Au)_2Te$; *muthmannite*, (Ag,Au)Te ; *sylvanite*, $AuAgTe_4$; *krennerite*, $(Au,Ag)Te_2$; *goldschmidtite*, Au_2AgTe_6 ; *calaverite*, $AuTe_2$; *antamokite*, a gold silver telluride ; *nagyagite*, $Au_2Sb_2Pb_{10}Te_6S_{15}$; *talapite*, $Bi(S,Te)_3AG_3$; *vondiestite*, $(Ag,Au)_5BiTe_4$; *goldfieldite*, $5CuS.(Sb,Bi,As)_2(S,Te)$; *arsenotellurite*, $Te_2As_2S_7$; *coolgardite*, a mixture of coloradoite, petzite, calaverite, and sylvanite ; *kalgoorlite*, a mixture of coloradoite, petzite, and tellurium ; *white tellurium*, an antimonial telluride of gold, silver, and lead ; and likewise also *Gelberz*, and *müllerite ;* and *henryite*, a mixture of lead telluride and pyrites. The oxidized minerals include the **tellurites**—*tellurite*, TeO_2 ; *durdenite*, $Fe_2(TeO_3)_3.4H_2O$, with a little selenium ; and *emmonsite*, a mixture of ferric tellurite, etc.—and the **tellurates**—*montanite*, $Bi(OH)_2TeO_4$; *magnolite*, Hg_2TeO_4 ; and *ferrotellurite*, $FeTeO_4$.

According to A. Cossa,[6] tellurium occurs among the eruption products of Vulcana, Lipari Islands. F. Zambonini and L. Coniglio observed it amongst the products of Vesuvius. E. Divers and T. Shimidzu found 0·17 per cent. of tellurium in the orange-red sulphur of Japan, and tellurium was also found in the chamber-mud of the sulphuric acid works at Osaka, Japan. D. Playfair observed about 0·002 per cent. of tellurium in the flue-dust of a furnace roasting Spanish pyrites. D. Forbes[7] reported 5·9 per cent. of tellurium in the native bismuth of Bolivia ; F. A. Genth, 0·042 per cent. ; and R. Schneider, 0·14 per cent. The presence of tellurium in commercial bismuth preparations—*e.g.* the oxynitrate—was discussed by

J. O. Braithwaite, E. Isnard, G. Brownen, M. Reisert, E. A. Letts, Bonz und Söhne, etc. The gold and silver ores of Colorado and other American States were discussed by C. Whitehead,[8] C. Vincent, H. J. Burkart, F. A. Genth, C. Palache, W. P. Headden, etc. E. Thomson found tellurium in Canada, in the ores of Montbray, Quebec. C. Rössler, and K. B. Heberlein found it in the silver ores of Spezia, Italy, when it occurs associated with platinum telluride; P. Krusch, and L. J. Spencer, in the gold ores of Kalgoorlie, West Australia; E. Weckwarth, near Quisque, in Peru; and it has also been reported in the gold ores of Offenbanya, Siebenbürgen. K. B. Heberlein found tellurium in the lead ores of Tasmania, and of Spezia, Italy; and C. H. Fulton, T. Egleston, E. Keller, and V. Lenher, in American copper ores. A. Schoep found up to 0·67 per cent. tellurium trioxide in fourmarierite. E. Priwoznik,[9] and S. Skowronsky made some general observations on the occurrence of tellurium.

§ 2. The Extraction of Tellurium

According to M. H. Klaproth,[1] native tellurium—containing, say, 97 per cent. of tellurium associated with iron, gold, and sulphur—can be dissolved in aqua regia; the soln. diluted with as much water as can be added without producing a precipitate, and treated with an excess of potash-lye. The filtrate is neutralized with hydrochloric acid. The precipitated tellurium dioxide is washed, dried, mixed with oil or with one-tenth its weight of charcoal, and heated in a glass retort. The reduced tellurium is found partly at the bottom of the retort, and partly as a sublimate.

J. J. Berzelius extracted tellurium from *tetradymite*—containing approximately 60 per cent. of bismuth, 36 of tellurium, and 4 of sulphur—by making the finely powdered ore into a stiff paste with sodium and potassium carbonates and olive oil; and heating the product, in a closed porcelain crucible, gradually to carbonize the oil, and afterwards to a white-heat. The object here is to separate the sulphur, selenium, and arsenic. The arsenic volatilizes and the sulphur and selenium remain in soln. after the tellurium has been precipitated by a current of air. The mass is cooled out of contact with air, quickly pulverized, quickly washed with air-free water, and a current of air passed through the filtrate to precipitate the tellurium. The filtrate containing tellurium sulphide (and selenide) and alkali sulphide is treated with hydrochloric acid to precipitate the tellurium. The washed tellurium is then fused, and distilled in a current of hydrogen so as to separate it from the gold, iron, manganese, and copper. F. Becker used a similar process. A. Schuller said that the distillation is easily conducted in vacuo. F. Wöhler found that the vacuum distillation in hydrogen removes the selenium as hydrogen selenide; and E. Priwoznik, that the selenium is similarly removed from molten tellurium in a current of hydrogen. J. J. Berzelius said that a trace of selenium always remains associated with the tellurium distilled in hydrogen. F. Stolba treated powdered tetradymite with hydrochloric acid to remove the limestone; and heated the washed residue with conc. hydrochloric acid, with the gradual addition of nitric acid, until the residue is white. As much water was added to the cold liquid as could be done without the separation of tellurium; iron was then added to the filtered soln., when crude tellurium, containing bismuth and copper, was precipitated. In another process, the powdered mineral was heated with sulphuric acid of sp. gr. 1·842 so long as sulphur dioxide was given off. The liquid was diluted with water, and the tellurium precipitated from the filtrate by means of iron; the residual matter was treated with conc. hydrochloric acid, and tellurium precipitated from the soln. by iron, or by sodium hydrosulphite. The tellurium was purified by dissolution in nitric acid, the liquid made alkaline with soda-lye, and the tellurium precipitated by glucose. The extraction of tellurium from bismuth ores was discussed by E. Matthey. E. Priwoznik, F. M. Horn, and J. Löwe employed modifications of the process for other minerals and ores. F. M. Horn dissolved the ore from the Allerheiligen Mine, Siebenburg, in boiling conc. sulphuric acid, and precipitated the silver with hydrochloric acid, and the tellurium by zinc.

J. J. Berzelius obtained tellurium from *silver telluride*—containing approximately 35 per cent. of tellurium, 46 to 61 of silver, and 1 to 18 of gold—by heating the powdered mineral in a current of chlorine, when silver chloride, and volatile tellurium tetrachloride are formed. There escapes a mixture of sulphur, selenium, and antimony chlorides. The tellurium tetrachloride is dissolved in dil. hydrochloric acid, and the tellurium precipitated by sodium hydrosulphite. The tellurium is purified by distillation in hydrogen. J. J. Berzelius also obtained tellurium by fusing the powdered ore with a mixture of potassium nitrate and carbonate in a silver crucible not quite to redness. When the black mass becomes reddish-grey, the temp. is increased to redness, and the mass allowed to cool. It is then lixiviated with water, and filtered. The clear liquid, which becomes turbid when heated, is evaporated to a small vol., mixed with a large proportion of powdered charcoal, and evaporated to dryness. The product is heated in a covered crucible, and then treated as in the extraction of tellurium from tetradymite. H. Hess employed a somewhat similar process. J. J. Berzelius also heated the native silver telluride with conc. nitric acid—free from chlorine. When all is oxidized, the liquid is evaporated to dryness; the dry mass extracted with water; and the residual tellurium dioxide mixed with sodium carbonate and oil as in the extraction of tellurium from tetradymite.

P. Berthier obtained tellurium from finely powdered *nagyagite*—containing approximately 30 per cent. of tellurium, and 50 per cent. of lead along with some gold, copper, antimony, and sulphur—by repeatedly boiling with conc. hydrochloric acid, and washing with boiling water; the residue was treated with nitric acid, and the decanted liquid evaporated to dryness; the resulting tellurium dioxide was dissolved in hydrochloric acid, and the tellurium precipitated with sulphurous acid. P. Berthier also fused the powdered mineral with a mixture of potassium nitrate and carbonate, and precipitated the tellurium from the acidified extract by means of iron. F. Stolba extracted the powdered mineral with hydrochloric acid, digested the residue with aqua regia, and added water so long as a precipitate—tellurium dioxide and antimony oxychloride—was formed. The gold was precipitated from the filtrate by ferrous sulphate, and the tellurium by iron in the presence of a little stannous chloride. The mixture of tellurium dioxide and antimony oxychloride was boiled with conc. soda-lye, and the tellurium precipitated from the alkaline liquor by glucose. According to B. Brauner, the precipitate obtained by diluting the above-indicated soln. with water may also contain basic tellurites which are not completely decomposed by the boiling soda-lye; if basic copper tellurite is formed, some copper may pass into soln., and be precipitated as cuprous oxide by the glucose. E. Donath, and L. Kastner used modifications of the process. J. Farbaky recommended the following process for extracting tellurium on a large scale from gold-tellurium ores:

The ore is slowly thrown into boiling conc. sulphuric acid, when lead, copper, zinc, tellurium, and also a portion of the silver compounds present go into soln., gold and silicic acid remaining undissolved. The product is then heated with water containing from 10 to 15 per cent. of hydrochloric acid, when the latter precipitates the dissolved silver and dissolves the hydrated tellurium oxide precipitated by the water. On filtering, a residue of gold and silver is obtained which is worked up separately. Sulphur dioxide is passed through the filtrate, and as this takes place in sulphuric or hydrochloric acid soln., only tellurium and selenium are thrown down. This residue is found to contain from 72–85 per cent. of tellurium, and after a repetition of the process, the percentage is increased to 97–98. The crude powder is melted and cast in moulds.

A. von Schrötter treated impure nagyagite with hydrochloric acid to remove soluble carbonates, etc.; and afterwards digested with aqua regia—with an excess of hydrochloric acid until the insoluble residue was white. Water, and hydrochloric acid were added to keep the tellurium dioxide in soln. The liquid was filtered from the silver chloride, and the soln. treated with ferrous sulphate, oxalic acid, or glycerol in a neutralized soln., to remove gold. The filtrate was treated with sulphur dioxide whereby scarlet-red selenium was first precipitated, and afterwards dark-grey tellurium. This was melted under a layer of sodium hydroxide. E. Priwoznik, F. M. Horn, H. Schnitzler, H. Schwarz, and J. Löwe used modifications of this process. W. Pethybridge discussed the extraction of tellurium from gold ores.

M. Shimose extracted tellurium from chamber-mud in the sulphuric acid works of Osaka, Japan, by digesting it with a warm soln. of potassium cyanide and sodium carbonate; the mixture was diluted with water and boiled; the filtrate was strongly acidified with sulphuric acid, treated with a little nitric acid, and the tellurium precipitated as sulphide by a current of hydrogen sulphide. The yellow sulphuric acid from the chambers was treated in a similar manner. The precipitates were melted with potassium cyanide, and the tellurium precipitated from an aq. soln. of the melted mass by the passage of a current of air. C. Whitehead said that the slimes obtained in the electrolytic refining of copper may contain much tellurium. The slimes are digested with hydrochloric acid, and the resulting soln. is decanted from the insoluble siliceous matters, and poured into water. Tellurium dioxide, along with some antimony oxychloride, is precipitated. The precipitate is dissolved in conc. hydrochloric acid and treated with sulphur dioxide when a red precipitate, consisting largely of selenium, separates out; the filtrate is diluted and again treated with sulphur dioxide when the tellurium is precipitated. The tellurium can be further purified by fusion with potassium cyanide when potassium telluride K_2Te is formed. A current of air is passed through the aq. soln. $2K_2Te+2H_2O+O_2=4KOH+2Te$. The precipitated tellurium is then fused and distilled in a current of hydrogen. Several of the tellurium ores can be treated with acid in a similar way, or fused with potash or soda, or with a mixture of sodium carbonate and potassium nitrate. In the case of the alkali fusion, the tellurate is extracted with water, treated with hydrochloric acid, and afterwards with sulphur dioxide, when glucose or sugar precipitates tellurium from soln. of alkali tellurates. Observations on this subject were made by E. Keller, V. Lenher, A. T. von Gersdorff and W. L. Kölreuter, A. Wehrle, and F. D. Crane. The extraction of tellurium from lead and silver ores was discussed by K. B. Heberlein.

P. Hulot fused the tellurate with potassium nitrate, and, on extracting the cold mass with water, there remained insoluble potassium tellurate, $K_2Te_4O_{13}$, which furnishes tellurium when suspended in water and reduced with nascent hydrogen from zinc and hydrochloric acid, or aluminium and alkali-lye.

R. W. E. MacIvor found that when the vapour of sulphur monochloride is passed over tellurium minerals—native tellurium, calcinite, etc.—the tellurium is volatilized as the tetrachloride. The solid is washed with carbon disulphide, dissolved in hydrochloric acid, and the tellurium precipitated by potassium hydrosulphite.

According to A. Gutbier, the above described methods of purification furnish crude tellurium contaminated with foreign metals—copper, silver, gold, zinc, arsenic, antimony, bismuth, iron, etc.—as well as by sulphur, selenium, silica, etc. Owing to the anomaly in the at. wts. of iodine and tellurium—**1**. 6, 6—tellurium has been tortured in numerous ways in order to find if the presence of a small proportion of some unsuspected impurity would account for the discrepancy. The element was obdurate—the results were nugatory. The impurities in selenium were removed by converting the selenium to the dioxide and heating the product nearly to its m.p. in air, when all but a trace of the selenium is volatilized as the dioxide; the sulphur and selenium can be removed by oxidizing the elements to telluric acid, etc., adding barium chloride to precipitated barium sulphate and selenate. H. Rose removed sulphur by heating the mixture with aqua regia, evaporating with hydrochloric acid, and precipitating the tellurium by sulphur dioxide. H. Rose also melted the crude tellurium with potassium cyanide in an atm. of hydrogen—

potassium telluride, selenocyanate, and sulphocyanate are formed. The telluride is then treated as indicated below for crude tellurium. A. Oppenheim observed that when the crude tellurium is heated on a water-bath with a soln. of potassium cyanide, only a little tellurium, but all the sulphur and selenium, pass into soln. Hydrochloric acid added to the soln. precipitates the selenium. A current of air passed through the soln. converts the tellurium into alkali tellurite and the soln., when treated with sulphur dioxide, gives a precipitate of tellurium. H. Rose, and M. Shimose added that tellurium is only slightly attacked by a boiling soln. and it passes into soln. in a form not precipitable by air, or by a hot soln. of potassium hydroxide and glucose, but which, like selenium, is precipitable by hydrochloric acid. A. von Schrötter, E. Priwoznik, C. Alexi, and M. Shimose said that when a conc. hydrochloric acid soln. is treated with sulphur dioxide, the selenium is first precipitated, and this is followed by grey tellurium. The process was discussed by J. J. Berzelius, E. Priwoznik, and A. von Schrötter. This subject has been discussed by E. Keller, and his results are summarized in Figs. 1 and 2 of the preceding chapter. F. D. Crane replaced the sulphur dioxide by hydrazine, hydroxylamine, or magnesium, but P. Köthner said that these precipitants offer no advantages over sulphur dioxide. E. Divers and M. Shimose worked with sulphuric in the place of hydrochloric acid. They said that selenium and tellurium are sharply distinguished from each other in their behaviour towards sulphur dioxide in the presence of sulphuric acid, and absence of hydrochloric acid. With precautions easy to be observed, the whole of the selenium is precipitated without a trace of the tellurium accompanying it. The sulphur dioxide soln. must be added to the undiluted or very slightly dil. soln. of the oxidized elements in conc. sulphuric acid. Some dilution of the sulphuric acid is indeed necessary, as the precipitation of the selenium is incomplete without it, but this is most safely and simply effected by the sulphur dioxide soln. itself. H. Rose said that the precipitation by sulphur dioxide in the presence of sulphuric acid alone is imperfect, but, added E. Divers and M. Shimose, this is only the case when the conc. of the sulphuric acid is too low. In the sulphuric acid process, the crude tellurium is heated with conc. sulphuric acid to form a colourless soln., and until no more sulphur dioxide is evolved ; four vols. of sulphurous acid are added, and only the selenium is precipitated.. The soln. is warmed on a sand-bath, diluted and filtered. The tellurium is then precipitated from the filtrate by adding hydrochloric acid, and passing a current of sulphur through the liquid. M. Shimose said that when an alkaline tellurite soln. is boiled with glucose, the tellurium is first precipitated and afterwards the selenium. F. Stolba made some observations on this subject.

B. Brauner purified tellurium by dissolving it in hydrochloric acid mixed with as little nitric acid as possible, and removing the nitric acid by repeated evaporation with hydrochloric acid. The soln., at 60° to 70°, is treated with sulphur dioxide to precipitate the selenium and tellurium which may be contaminated with lead or copper. The dry product is fused with five times its weight of potassium cyanide in an atm. of hydrogen to protect it from air. The cold mass is extracted with water, and a current of air passed through the claret-red soln. of potassium telluride. The washed and dried precipitate of tellurium is distilled in a current of hydrogen.

According to P. Köthner, tellurium may be separated from its common impurities (copper, silver, gold, bismuth, antimony, arsenic, and selenium) by dissolving the crude substance in hydrochloric acid containing a little nitric acid, evaporating off the excess of the latter reagent, diluting the cooled soln. with water until the deep yellow colour of tellurium tetrachloride disappears, filtering from the precipitate of silver chloride and the oxychlorides of antimony and bismuth, and treating the warm filtrate with sulphur dioxide. The treatment is repeated, and by fractional precipitation two or three times, and collecting the middle fraction, pure tellurium is obtained. The first fractions contain arsenic, whilst the third fraction shows traces of copper and gold. The element may be obtained in a crystalline form by passing sulphur dioxide into a hot soln. of the tetrachloride in conc. hydrochloric acid (20·3 per cent.); the crystals being opaque with a silvery lustre.

L. Staudenmaier obtained tellurium of a high degree of purity by dissolving freely powdered crude tellurium in dil. nitric acid; evaporating the soln. with conc. nitric acid, and filtering. The tellurium is then precipitated with sulphur dioxide, and washed with hydrochloric acid and water. It is then dissolved in an excess of dil. nitric acid, and a slight excess of chromic acid is added. The soln. is evaporated for crystallization, with the crystals washed with nitric acid and dissolved in a small quantity of water. The soln. is treated with a few drops of alcohol to reduce any chromic acid remaining, and precipitated by the addition of nitric acid. Finally, the product is dissolved in water and evaporated to dryness on the water-bath—telluric acid remains. This reduces to tellurium dioxide when heated, and it can be reduced to tellurium by heating it in hydrogen, or by the action of sulphur dioxide. P. Köthner said that this product still contains spectroscopic traces of copper and silver.

D. Klein and L. Morel dissolved the tellurium in conc. nitric acid, and evaporated the soln. for crystallization. The basic nitrate crystallizes out leaving the other metal nitrates in soln. The product after washing with hot water, is heated to form tellurium dioxide. This is dissolved in hydrochloric acid, and the tellurium precipitated with sulphur dioxide. J. F. Norris, H. Fay and D. W. Edgerly dissolved the oxide obtained from the purified basic nitrate in hydrochloric acid, precipitated the tellurium with sulphur dioxide, and distilled the resulting metal. P. Köthner said that the basic nitrate is conveniently prepared by dissolving small quantities of tellurium in a slight excess of nitric acid and evaporating the soln. obtained from several experiments. In this way, the separation of tellurium is reduced to a minimum. This salt, however, even after repeated crystallization, still contains traces of silver and copper. According to P. Köthner, tellurium can be separated from all other elements except antimony by distillation in a vacuum, and since this element is removed in purifying the basic nitrate, it follows that a combination of the two processes should lead to the production of pure tellurium. The product obtained by reducing the recrystallized nitrate with sulphur dioxide is distilled under 9–12 mm. press. in a tube divided into segments by asbestos partitions. After repeated distillation through three or four of these compartments a specimen is obtained which is quite free from impurities. G. W. A. Kahlbaum and co-workers, and F. Krafft and L. Merz also purified the element by distillation in vacuo. K. B. Heberlein treated the crude tellurium with nitric acid (or aqua regia or, if lead was present, with boiling conc. sulphuric acid), and added an excess of aq. ammonia—the lead, bismuth, iron, etc., are precipitated as tellurites, and the filtrate was treated with an ammoniacal soln. of an ammonium magnesium salt. White magnesium tellurite was precipitated. The washed precipitate was dissolved in a little hydrochloric acid, and reprecipitated by aq. ammonia. The tellurium was precipitated from the hydrochloric acid soln. of this product by sulphur dioxide. R. Schelle boiled the crude tellurium with powdered sulphur and a soln. of sodium sulphide, and added sodium sulphite when a greyish-black precipitate of pure tellurium was obtained. Selenium, arsenic, tin, gold, and platinum are not precipitated by this method, but copper is removed by the initial treatment with sodium sulphide. F. Krafft and R. E. Lyons prepared diphenyl telluride, $Te(C_6H_5)_2$, by treating tellurium with diphenyl mercuride. O. Steiner purified this product by fractional distillation in vacuo. G. Pellini converted the purified diphenyl telluride into dibromide which was then purified by recrystallization from benzene; the dibromide was converted into telluric acid; this was reduced to tellurium, and the product distilled in vacuo.

C. Himly used an electrolytic process for purification. The cathode was made by dipping a platinum wire into molten tellurium; and it was surrounded by a woollen or linen bag; the anode was of platinum; the electrolyte, dil. potash-lye. The potassium telluride formed at the cathode is oxidized to tellurite by the oxygen at the anode. According to C. Whitehead, tellurium is readily deposited by an electric current either from an acid or alkaline soln. It has been found possible to separate tellurium from copper by adding an excess of sodium hydroxide and about 3 grms. of potassium cyanide for each grm. of copper present, and passing an electric current through the soln.; the tellurium is thrown down as a black, non-adherent precipitate which can readily be filtered off; the soln. can then be slightly acidified with sulphuric acid and the copper estimated in the usual way by electrolysis. According to F. C. Mathers and H. L. Turner, tellurium can be deposited from a soln. of 300 grms. of tellurium dioxide (49·6 per cent. TeO_2 and 46·1 per cent. Na_2TeO_3), 500 grms. of 48 per cent. hydrofluoric acid, and 200 grms. of sulphuric acid per litre, using 1·6 amp. per sq. dm. at a lead cathode at ordinary temp. The tellurium anode dissolved and the 0·9 per cent. of selenium remained in the slimes. The deposited tellurium is light grey and brittle. The deposits are less satisfactory if hydrochloric acid be substituted for hydrofluoric acid.

J. J. Berzelius[2] referred to the blue liquid containing finely-divided tellurium which is obtained when a very dil. soln. of potassium telluride is exposed to air; and B. Brauner, to the blue, greenish-blue, or violet liquid obtained by the action of sulphurous acid on a hydrochloric acid soln. of tellurium dioxide. A. Gutbier obtained **colloidal tellurium** by reducing a dil. soln. of tellurous or telluric acid by means of hydrazine hydrate, phenylhydrazine, hydroxylamine hydrochloride, hypophosphorous acid, sulphurous acid, sodium hydrosulphite. If the reduction occurs in the presence of gum arabic, or an extract of the seeds of *Plantago psyllium*, the hydrosol is *ausserordentlich beständig*. L. Lilienfeld used gelatin, gum arabic, and proteins as protective colloids. A. Gutbier and F. Resenscheck found that when an aq. soln. of telluric acid containing potassium cyanide is electrolyzed with a current of 0·5 amp., the soln. gradually becomes brownish-violet owing to the formation of tellurium in the hydrosol form; as the electrolysis is continued, the tellurium separates as a flocculent precipitate. When ammonium oxalate is substituted for potassium cyanide, the steel-blue hydrosol of tellurium is first of all formed. By dialysis, the new brownish-violet hydrosol form may be obtained in brilliantly-coloured soln., which are not decomposed after six months. According to C. Paal and C. Koch, the brown modification of colloidal tellurium is easily obtained by warming an alkaline aq. soln. of telluric acid, containing protalbic or lysalbic acid, with hydrazine hydrate on the water-bath; in neutral or alkaline soln., containing sodium protalbate or lysalbate, telluric acid is reduced by hydroxylamine only on boiling, as is tellurium dioxide by hydrazine hydrate; in these cases, the brown modification, at first formed, changes into the blue as the boiling proceeds. A. Gutbier and F. Resenscheck's brownish-violet tellurium hydrosol is probably a mixture of the brown and blue modifications. As in the case of colloidal selenium, the liquid hydrosols of tellurium, containing sodium protalbate or lysalbate, are very stable, and, on careful evaporation, yield the solid hydrosols, which are soluble in water and remain unchanged when heated to 100° in vacuo. On addition of acetic acid to the liquid hydrosols, the solid hydrosols containing protalbic or lysalbic acid are precipitated; these contain upwards of 80 per cent. of tellurium, and are very stable when protected from the atm. oxygen, the brown modification retaining its solubility after three years. P. P. von Weimarn and B. V. Maljisheff obtained colloidal tellurium by adding 0·1 grm. of the element to 5 c.c. of a boiling soln. of potassium hydroxide, sat. at the ordinary temp., and adding the soln. of the metal thus formed to 1000 c.c. of cold water, the mixture being stirred vigorously. The stability of the colloidal tellurium soln. depends directly on the peptization processes, and can be greatly increased. The soln. can also be made more stable by the addition of gelatin or similar substances. C. Levaditi found that a 30 per cent. aq. soln. of dextrose added to a 5 per cent. aq. soln. of sodium tellurite, and heated to boiling for half an hour, furnishes colloidal tellurium.

G. Bredig obtained a colloidal soln. of tellurium by the cathodic spluttering of the element. E. Müller and R. Lucas found that with an applied e.m.f. of four or more volts, in water, a tellurium cathode loses weight, and yields a colloidal soln. of tellurium. The very dil. soln. are reddish-violet in colour, the more conc. soln. are brown and opaque. The tellurium goes into soln. with an apparent valency of about 1·2, which indicates that the pulverization is not merely mechanical. The dissolution is independent of the presence of oxygen in soln. and is therefore not due to oxidation of tellurium hydride. No hydrogen is evolved at the tellurium cathode. The phenomena may be explained by assuming that the tellurium goes into soln. in the form of the Te'-ion, which then passes into bivalent tellurium ions either by direct assumption of a second charge from the electrode or by the reaction $2\mathrm{Te}'=\mathrm{Te}+\mathrm{Te}''$. In alkaline soln., the pulverization takes place also, but alkali polytellurides are also formed. In acidic soln., hydrogen is evolved and only a trace of pulverization can be observed, the discharge potential of hydrogen in the acidic soln. being lower than that required for the dissolution of tellurium. A. Gutbier and B. Ottenstein prepared a sol of tellurium by reducing telluric acid with dextrose in the presence of ammonia. The presence of tellurous acid, and absorbed dextrose, even after dialysis, probably makes the sol very stable. They also obtained a purple colour by depositing the colloid in stannic hydroxide. E. Fouard obtained colloidal tellurium by electrolyzing a soln. of a salt of the metal containing a pure organic colloid (albumin, starch, or gelatin) with a current of a few milliampères. At the cathode the metal ions are neutralized by the repelled negatively-charged colloid micelles. A colloidal organo-metallic complex is thus formed. The anode is separated by immersion in a collodion cell rendered semi-permeable by precipitated copper ferrocyanide. The cathode should be a bad conductor, so as to reduce the frequency with which formation of the complex occurs on the cathode. The flocculation of the colloidal soln. by boiling or by the addition of electrolytes was studied by A. Gutbier, C. Paal and C. Koch, W. Biltz, J. J. Doolan, etc. S. Utzino observed that the maximum stability of colloidal tellurium ground in the so-called colloid mill, is not necessarily obtained with the finest subdivision. R. Auerbach studied the coloured soln. of tellurium in sulphuric acid—*vide infra*, oxysulphates. A. Gutbier and B. Ottenstein said that the colloidal particles are negatively charged. W. Reinders discussed the distribution of the colloid between two liquid solvents.

§ 3. The Physical Properties of Tellurium

J. J. Berzelius[1] described tellurium cooled from the molten state, as a tin-white crystalline mass with a metallic lustre, and added that it is brittle and easily powdered ; and R. Schelle added that after fusion tellurium is silver-white, and if fused in sodium hydrosulphate, and cooled in carbon dioxide, a crystalline star resembling that of antimony is formed. A. W. Wright said that a thin film is dull purple ; and D. Gernez, that the vapour is golden-yellow or orange-yellow. G. Magnus said that tellurium usually occurs massive—columnar or granular—dark grey or black in colour. J. C. L. Schröder van der Kolk said that the streak of tellurium is reddish violet-grey. When precipitated by the action of air on a dil. soln. of potassium telluride, by the addition of water to a conc. sulphuric acid soln., or by the action of sulphur dioxide on a soln. of a tellurite, it furnishes a brown powder. N. W. Fischer observed that the tellurium precipitated by metals—*e.g.* zinc, tin, iron, etc.—from a soln. of tellurium dioxide in hydrochloric acid as a black powder, which has a metallic lustre when rubbed with a burnishing tool ; if precipitated by lead, the tellurium is dendritic. D. Beljankin said that tellurium precipitated from alkaline soln. consists of microscopic rhombohedra. L. P. Sieg said that a film of spluttered tellurium probably consists of crystals few or many in number. W. Phillips made some observations on the natural crystals, and G. Rose showed that the natural crystals are trigonal with the axial ratios $a : c = 1 : 1{\cdot}3298$; and observations were made by A. Breithaupt, F. A. Genth, L. Tokody, G. vom Rath, A. des Cloizeaux, J. Loczka, H. von Foullon, and G. Rolland. C. Haushofer, and F. Fouqué and A. Michel-Lévy, described the sublimed crystals as rhombohedra, and G. W. A. Kahlbaum, as hexagonal prisms. G. Rose, and C. W. Zenger said that the crystals obtained by freezing the molten metal are rhombohedra. J. Margottet gave $a : c = 1 : 1{\cdot}33595$ for the axial ratio of the artificial crystals. G. Rose represented the hexagonal prisms of the natural crystals by Fig. 1, and the crystals may also be acicular and those obtained from soln. of potassium or ammonium telluride are also needle-like, Fig. 2.

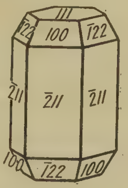

FIG. 1.—Natural Crystal.

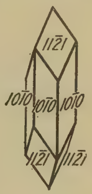

FIG. 2.—Crystal precipitated from Potassium Telluride.

The crystals show signs of twinning. The ($\bar{2}11$)-cleavage is complete, and the

(111) cleavage is incomplete. L. P. Sieg found that a spluttered tungsten film has a crystalline structure. The **X-radiograms** obtained by A. J. Bradley corresponded with crystals having a space-lattice with a simple trigonal structure having inter-axial angles almost 90° in which each atom is slightly displaced towards two of the six adjacent atoms. This furnishes a threefold spiral composed of three inter-penetrating simple triangular lattices—*vide* selenium. M. K. Slattery found that both elements crystallize in a simple triangular lattice with 3 atoms associated with each point of the lattice. The side *a* of the basal triangle is 4·44 A.; the height, *h*, is 5·912 A.; the axial ratio, *c*, 1·33, and the density, 6·25. The arrangement of the atoms in the space-lattice about the prism edge, *h*, forms an ascending helix, with a threefold symmetry, so that each atom is exactly above the third atom below in the same helix. The X-radiogram does not distinguish between a right- and left-handed screw. The prisms edge is thus a screw-axis; and the interactions of the screw-axis with the basal plan, form the unit basal triangles. The radius of the helix is 1·20 A., so that this represents the distance from the centre of each atom to the axis of the helix. The shortest distance between the atoms in the same helix, 2·86 A., is less than 3·46 A., the shortest distance between atoms in different helices. This means that the atoms in the same helix are held together by cohesive forces much greater than those binding atoms in different helices, and that the crystal is harder in the direction of the screw axis than perpendicular to it. The uniqueness of this axis was emphasized by A. J. Bradley, and R. F. Mehl and B. J. Mair, who showed that it accounts for many of the directional properties of the two elements, and that crystallization is probably preferential along this line. This was shown to be the case by P. W. Bridgman, who found that the trigonal or screw axis lies longitudinally in the casting—*vide infra*. S. von Olshausen, and G. Wassermann made some observations on this subject; the data were also summarized by P. P. Ewald and C. Hausmann. W. Hume-Rothery studied the lattice-constants of the elements.

It is not probable that **isomorphism** exists between tellurium and arsenic, antimony, and bismuth; but tellurium is isomorphous with the trigonal form of selenium. The isomorphism with selenium was discussed by G. Rose, C. F. Rammelsberg, P. Groth, W. Muthmann, etc. J. W. Retgers studied the isomorphism of sulphur, selenium, and tellurium, and concluded that while sulphur and selenium showed complete crystal similarity, tellurium was isomorphous with neither element. No isomorphous mixtures are formed between potassium tellurate on the one hand, and with potassium sulphate, selenate, chromate, molybdate, tungstate, manganate, or ferrate on the other hand. Nor could J. F. Norris and W. A. Kingman prepare isomorphous hydroselenates and hydrotellurates. The only case of isomorphism known to J. W. Retgers was that between the sulphides, selenides, and tellurides, which crystallize in the cubic system, but he argued that the crystals in this system have such a high degree of crystallographic symmetry that their power to form mixed crystals is not a satisfactory proof of true isomorphism. Potassium tellurate is not isomorphous with the selenate, but it is isomorphous with the osmiate. This with the atomic weight of tellurium has been used as an argument for placing tellurium in the eighth group. The isomorphism of compounds of the type K_2TeBr_6—where bromine may be replaced by chlorine, and potassium by ammonium, rubidium, or cæsium—observed by H. L. Wheeler, and W. Muthmann with the corresponding selenium compound and with the analogous platinum salt, is also a result of all crystallizing in the cubic system. J. F. Norris and R. Mommers found that the double bromide of platinum and dimethylamine, crystallizing in the orthorhombic system, is isomorphous with the analogous compounds of selenium and tellurium, and this case of isomorphism is not open to the objections raised by J. W. Retgers; and similar remarks apply to the isodimorphism of G. Pellini's diphenyl dibromotelluride, $(C_6H_5)_2TeBr_2$. F. Krafft and O. Steiner discussed the mutual replacement of sulphur, selenium, and tellurium in this family of elements. G. Pellini and G. Vio, and Y. Kimata found that the f.p. curve of mixtures of selenium and tellurium show that solid soln. are formed in agreement with the isomorphism of the trigonal forms of these two elements—*vide* tellurium selenide in the preceding chapter. G. Pellini also came to a similar conclusion with respect to sulphur. Some of the isomorphous crystals have the form of rhombic sulphur. A similar conclusion was drawn by E. Billows. The structure of the crystals of tellurium was discussed by V. M. Goldschmidt.

From the **vapour density** at 2100°, H. von Wartenberg found the **molecular weight** to be 160. E. Moles found the mol. wt. deduced from the f.p. and conductivity of soln. in sulphuric acid to be abnormal. A. Jouniaux inferred that tellurium is monatomic at 357° and more complex at lower temp.; it is diatomic at about 1500°. For the mol. wt. in iodine soln., *vide infra*, tellurium halides. R. Auerbach's cryoscopic observations showed that tellurium dissolves as Te in pyrosulphuric acid. The **specific gravity** of native tellurium varies with its degree of purity. Thus, J. Loczka gave 6·084; R. W. E. MacIvor, 6·2; V. R. von Zepharovich, 5·86; and F. A. Genth, 6·275. For the artificial crystals M. H. Klaproth gave 6·115; F. J. Müller von Reichenstein, 6·393; J. Löwe, 6·180; E. Matthey for 98·7 per cent. Te, 6·27; G. Magnus, 6·1379; and D. Klein and L. Morel, 6·204–6·215. J. J. Berzelius gave 6·245 for the average of five determinations of crystals obtained from the molten element, but preferred the higher value 6·258 because of pores. E. Priwoznik gave 6·2459 at 18·2° for a sample which had been melted in hydrogen, and C. F. Rammelsberg, 6·38 to 6·42; D. Beljankin gave 6·338 at 18°–22°; and H. Fay and C. B. Gillson, 6·243. For distilled tellurium, V. Lenher and J. L. R. Morgan gave 6·194 to 6·204—mean 6·199, and G. W. A. Kahlbaum, 6·23538 at 20°. D. Beljankin gave 6·157 for the sp. gr. of tellurium precipitated from alkaline soln.; and 6·015 at 20° for amorphous precipitated tellurium. C. F. Rammelsberg gave 5·93 for the sp. gr. of the amorphous tellurium precipitated by sulphur dioxide; he added that the amorphous tellurium suffers no change if heated to 300°. W. Spring gave for tellurium which had been subjected to high compression, as well as for the element which had not been compressed:

		0°	20°	40°	60°	80°	100°
Sp. gr.	Not compressed	6·2322	6·2194	6·2052	6·1500	6·1366	6·0640
	Compressed .	6·2549	6·2419	6·2294	6·2170	6·3030	6·1891

M. L. Huggins calculated for the **atomic radius,** 2·46 A.; J. C. Slater, 1·22 A.; and W. F. de Jong and H. W. V. Williams, 1·33 A. W. L. Bragg calculated 1·33 A. for the at. radius; A. Ferrari, 3·025 A. E. T. Wherry gave 0·81 to 0·89 A. for quadrivalent tellurium, and 0·56 A. for sexivalent tellurium. F. H. Burstall and S. Sugden discussed the parachor of some bivalent tellurium compounds.

V. Lenher and co-workers said that the metal expanded slightly after solidification. E. Cohen and J. F. Kröner[2] observed that the treatment to which tellurium has been subjected greatly influences the sp. gr., and it varies between 6·272 and 5·949. Tellurium, prepared by the reduction of telluric acid by hydrazine sulphate, had a sp. gr. of 3·242. This low value was traced to occluded nitrogen. They assume that tellurium exists in two forms present as **dynamic allotropes** in equilibrium α–Te$\rightleftharpoons\beta$–Te. The variety with the smaller sp. gr. is stable at the higher temp. Thus, the sp. gr. of a sample before heating to 350° was 6·233, and after heating to this temp., 6·203. A. Damiens said that observations on the sp. gr. of tellurium purified by distillation in vacuo, and either sublimed, or slowly cooled from the molten state, lend no support to E. Cohen and J. F. Kröner's theory of dynamic allotropy. Sublimed tellurium of sp. gr. 6·310 is not changed by prolonged heating at various temp. Tellurium prepared in other ways may appear to have a smaller sp. gr. owing to its porosity. Amorphous tellurium, of sp. gr. 5·85 to 5·87, is transformed by heat into crystalline tellurium, and heat is evolved during the transformation. W. Haken reported that the electrical conductivity indicated the existence of two allotropic forms with a transition temp. at 354°; but A. Damiens inferred from observations on the sp. gr., rate of cooling and heating, sp. ht. and heat of reaction, that the analogy between the **allotropy** of sulphur and tellurium does not apply since tellurium is characterized by the existence of a single crystalline form. Attempts by H. Staudinger and W. Kreis to prepare solid red tellurium by cooling the vapour at 1000° in liquid air were unsuccessful. C. del Fresno, and I. I. Saslavsky studied the at. vol. of tellurium in its compounds. L. S. Ramsdell calculated 1·27 A. for the atomic radius ; H. G. Grimm made observations on this subject.

M. Toepler [3] observed an irregularity in the vol. changes of tellurium as it cools from the molten state, and this he attributed to the formation of an amorphous plastic variety of tellurium just before it solidifies. J. R. Rydberg gave 2·3 for the **hardness** of tellurium (diamond 10). P. Saldau gave 18·43 kgrms. per sq. mm. for the hardness of tellurium when that of lead is 3·92 kgrms. per sq. mm. E. Schmid and G. Wassermann discussed the percussion figures of the crystals, and also the plastic deformation. P. W. Bridgman found the cubic **compressibility** to be 0·0000024 kgrm. per sq. cm.; **Poisson's ratio,** 0·33 ; the **tensile strength** expressed as a breaking load in tension was 115 kgrms. per sq. cm. A piece of tellurium wire 8 cms. long and 0·0348 cm. diameter, fastened rigidly at one end, and bent by a weight at the other, showed a maximum permanent set of 0·11 cm., and broke under a deflection of 1·82 cm. The brittleness is extreme for a metal, but is not as high as for glass. P. W. Bridgman measured the **elastic constants ;** he found the initial linear compressibility, p in kgrms. per sq. cm., for angle crystals to be, at 30°, $-4{\cdot}14\times10^{-7}$ when parallel, and $27{\cdot}48\times10^{-7}$ when vertical to the trigonal axis ; at 30°, when perpendicular to the trigonal axis $-\delta l/l=27{\cdot}48\times10^{-7}p-52{\cdot}7\times10^{-12}p^2$ at 30°, and at 75°, $27{\cdot}7\times10^{-7}p-53{\cdot}6\times10^{-2}$ at 75° ; at 75°, when parallel to the trigonal axis, $+\delta l/l=4{\cdot}137\times10^{-7}p-9{\cdot}6\times10^{-12}p^2$, and at 75°, $5{\cdot}132\times10^{-7}p-13{\cdot}2\times10^{-12}p^2$. The remarkable fact is that the compressibility along the trigonal axis is negative, so that when the crystal is subjected to hydrostatic press. all over, it elongates along the trigonal axis. The cubic compressibility is normal $-\delta v/v_0=50{\cdot}82\times10^{-7}p-101{\cdot}1\times10^{-12}p^2$ at 30°, and $50{\cdot}41\times10^{-7}p-85{\cdot}6\times10^{-12}p^2$ at 75°. The cubic compressibility thus decreases with rise of temp. R. F. Mehl and B. J. Mair explain this as follows :

> It is evident that this crystal structure is not closely packed, and it is conceivable that a change in either of the major dimensions, that of the side of the unit basal triangle, a, or that of the prism edge, h, should cause a change in density resulting merely from a difference in the closeness of the packing of the atoms, the two inter-atomic distances remaining unchanged. In such a process a lengthening of the prism edge, h, would cause a shortening of a and also a shortening of the radius of the helix. If such an elongation would result in an increase in density, it is entirely reasonable to suppose that an increase in press. tending towards an increase in density, would in fact cause a lengthening of this axis, with an attendant shortening of the other two dimensions. Such a lengthening would obviously cause the abnormal coeff. observed by P. W. Bridgman. Fig. 3 shows a curve representing density as a function of the height of the unit prism. The values from which the curve was plotted were calculated by taking a series of values for h and keeping the inter-atomic distances, 2·86 A. and 3·46 A., unchanged, calculating the radius of the helix and the side of the unit basal triangle, a, and from these the density of the hypothetical crystal. The curve passes through a minimum at a density slightly greater than 6·20, corresponding to a value for h of 5·55 A. For a prism of height less than 5·55 A. an increase in press. tending to cause an increase in density could do so only by shortening h, the two interatomic distances remaining unchanged, and the screw-axis would therefore show the usual positive compressibility coeff. On the other hand, if the value for h lay to the right of 5·55 A. an increase in press. would cause a lengthening in h, since such a process would result in an increase in density. The actual value of h for tellurium, indicated by the arrow in the

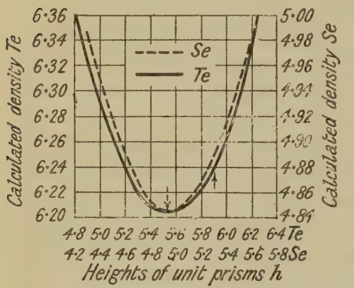

FIG. 3.—Calculated Densities of Tellurium and Selenium with Space-Lattices of Different Heights.

figure, is 5·91 A. and is therefore to the right of the minimum, so that an increase in press. should cause an increase in h, or, in other words, a negative compressibility coeff. along this axis.

Measurements have not been made with selenium, but R. F. Mehl and B. J. Mair, applying the same argument, state:

> The actual value for h, indicated by the arrow, dotted line, Fig. 3, appears to lie very slightly to the left of the minimum, and therefore, the height of the unit prism would very likely decrease with the application of press. (assuming, of course, that the lattice dimensions used in the calculations are correct); but since the screw-axis is in a state of greater compression than the triangular axes the compressibility along this axis is probably low. Resisting the elongation (or contraction) of the helix upon the application of press., there is the tendency within the lattice to maintain the angle formed by any three atoms in the same helix at (for tellurium) 126·5°, and this tendency doubtless becomes more and more urgent as the angle departs further and further from this value, so that it may be assumed that the adjustment of density by the lengthening or shortening of the helix meets with increasing resistance as the press. rises. It is this restraint which prevents the helix from straightening completely upon the first application of press.

H. Fizeau gave $\alpha=0{\cdot}00001675$ for the coeff. of **thermal expansion**—linear—between 0° and 40°; and 0·00001732 between 0° and 50°; whilst W. Spring gave for coeff. of cubical expansion $0{\cdot}0_43440$ between 0° and 20°; $0{\cdot}0_43737$ between 0° and 60°; and $0{\cdot}0_43687$ between 0° and 100°. P. W. Bridgman gave for the linear thermal expansion at 20°—$1{\cdot}6\times10^{-6}$ when parallel and $27{\cdot}2\times10^{-6}$ when perpendicular to the trigonal axis. E. Jannetaz found that the ratio of the sq. root of the **thermal conductivity,** k_γ, in the direction of the principal axis, and k_a, in the direction of the base, is $(k_a/k_\gamma)^{\frac{1}{2}}=0{\cdot}81$. H. Kopp gave 0·0475 for the **specific heat;** H. V. Regnault, 0·0474 for distilled tellurium, and 0·0516 for that precipitated by sulphur dioxide; M. Berthelot and C. Fabre gave 0·0483 for fused tellurium slowly cooled, 0·0524 for that precipitated by sulphur dioxide, and 0·0518 for that distilled in a current of sulphur dioxide; A. Wigand, for crystalline tellurium between 15° and 100°, gave 0·0483, and for amorphous tellurium, 0·0525; and G. W. A. Kahlbaum and co-workers, 0·04878 for that distilled in vacuo. W. A. Tilden gave 0·0469 between —182° and 15°; 0·0483, between —15° and 100°; 0·0487, between —15° and 200°; and 0·0500, between —15° and 380°. J. Dewar gave 0·0288 between —253° and —196°. The corresponding **atomic heats** are 3·68 between —253° and —196°; 5·98 between —182° and 15°; 6·16 between 15° and 100°; and 6·38 between 15° and 380°. E. Adinolefi[4] found that the sp. ht. of tellurium is increased by about 8 per cent. after exposure to the X-rays, and this is attributed to a change in the structure of the element. The relations of the sp. ht. were studied by I. Maydel.

T. Carnelley and W. C. Williams found the **melting point** of tellurium to be between 452° and 455°; R. Pictet, 525°; H. Fay and co-workers, and S. Umino, 446°; K. Mönkemeyer, 428°; W. Guertler and M. Pirani, 450°; H. Pélabon, 452°; W. R. Mott, 452°; W. Biltz and W. Mecklenburg, 455°; M. Chikashige, 438°; M. Kobayashi, 437°; and E. Matthey, for 97·0 per cent. Te, 450°. A. Damiens gave 453° for the m.p., and observed no break in the heating or cooling curve between this temp. and the ordinary temp. W. Guertler and M. Pirani gave 450° for the best representative value. A. Simek and B. Stehlik gave 452° for the m.p. in vacuo; in hydrogen, the m.p. is lowered 0·15°, and in carbon dioxide 0·2°. There is a marked contraction during the freezing of the mother-liquid, and with slow cooling, a cavity is formed in the middle of the mass; and if quickly cooled, the surface freezes first, and numerous small cavities form in the interior. If tellurium be melted in a glass vessel, the glass is inclined to shatter on cooling owing to the formation of pores between the crystals producing an apparent expansion. H. Carlsohn found that the m.p. of tellurium compounds does not follow the additive rule. J. J. Berzelius said that tellurium boils at a temp. higher than the softening temp. of glass, and it is converted into a yellow vapour, the colour of chlorine. M. H. Klaproth added that when heated to redness in a retort, the tellurium sublimes into the neck in the form of shining drops. F. Wöhler, and A. Oppenheim distilled the element in a porcelain retort at a red-heat, J. J. Berzelius distilled it in a current of hydrogen; and A. Schuller obtained well-defined crystals by distillation in vacuo. L. Staudenmaier observed that a little volatilization occurs at 300°; H. St. C. Deville and L. Troost gave 1390° for the **boiling point**; and W. R. Mott, 1390°; while F. Krafft and L. Merz added that in the vacuum of a cathode light marked sublimation occurs at 430°, and the b.p. at 58 mm. press. is 478°. J. Joly observed that sublimation of tellurium dioxide occurs at 850° with native tellurium, and at 700° with purified tellurium; and of the monoxide, respectively at 525°, and 470°. J. J. Doolan and J. R. Partington found the **vapour pressure** of tellurium to be 0·0186 atm. at 671°; 0·00440 at 578°; and 0·000610 at 488°. The corresponding latent **heat of volatilization** is 24·7 Cals. per mol. between 578° and 671°, and 28·2 Cals. per mol. between 488° and 578°—assuming the diatomic Te_2-molecule. The mean value is 26·5 Cals. per mol. H. Biltz obtained a **vapour density** of 9·13 at 1880° corresponding with the Te_2-molecule. He added that H. St. C. Deville and L. Troost's determinations are inaccurate. H. Pélabon calculated the latent **heat of fusion** to be 20 to 21 Cals. per mol. W. Herz gave 7·4 Cals. per gram; and S. Umino, 33·5 cals. per mol. J. J. van Laar discussed the equation of state of the solid.

M. Berthelot and C. Fabre found the **heat of solution** of tellurium in bromine and bromine water is 66·7 Cals. in the case of crystalline tellurium; 42·6 Cals. in the case of tellurium precipitated by sulphur dioxide; 66·7 Cals. for tellurium precipitated by oxygen from potassium telluride; and 67·0 Cals. for tellurium separated by oxygen from hydrogen telluride. Tellurium separated from ferric chloride by hydrogen telluride is crystalline. Tellurium rapidly cooled from the molten state develops 41·4 to 58·1 Cals. indicating that it is an indefinite mixture of amorphous and crystalline tellurium. The calculated **heat of crystallization** from amorphous selenium is thus 12·096 cals. for 64 grms., but A. Damiens obtained 2·63 cals. for this constant. S. Umino gave 0·63 cal. per mol. for the **heat of transformation** at 348°. G. N. Lewis and co-workers gave 12·8 for the **entropy** of tellurium at 25°, and B. Bruzs, 17·2 at the m.p. E. Kordes calculated 1·63 for the ratio $Q_{\text{cals.}}/T$ for Te, and 6·52 for Te_4. W. Herz studied the subject. J. Franck calculated 69 Cals. for the work of dissociation of Te_2; and V. Kondrateeff, 65 Cals.

C. Cuthbertson and E. P. Metcalfe [5] found the **index of refraction** of tellurium vapour to be 1·002620 for $\lambda=546_{\mu\mu}$; 1·002495 for $\lambda=589{\cdot}3_{\mu\mu}$; and 1·002370 for $\lambda=656{\cdot}3_{\mu\mu}$. R. F. Miller found that the refractive indices for single crystals with the light parallel and perpendicular to the plane of incidence are, respectively, 1·9 and 1·7. The whole range of wave-length, L. P. Sieg and G. D. van Dyke gave 2·50 to 3·14 and 2·05 to 2·68 respectively when the light falling on one of the hexagonal faces is polarized with the electric vector respectively parallel and perpendicular to the principal crystal axis. The absorption constants are respectively 0·40 to 0·56, and 0·54 to 0·67. Observations were also made by A. H. Pfund, and E. O. Hulburt. W. W. Coblentz gave for the percentage **reflecting power,** R, of tellurium for rays of wave-length λ:

λ . .	0·6μ	0·8μ	1·0μ	2·0μ	4·0μ	7·0μ
R . .	49	48	50	52	57	68 per cent.

R. F. Miller found that the reflecting powers of single crystals with the crystal axis parallel and perpendicular to the plane of incidence respectively are 2·9 and 2·7 over the whole range of wave-lengths; L. P. Sieg and G. D. van Dyke gave 0·28 to 0·34 and 0·26 to 0·30 when the light falling on one of the hexagonal faces is polarized with the electric vector respectively parallel and perpendicular to the principal crystal axis. From observations on the halides and organic tellurium compounds, G. Pellini and A. Menin found the **atomic refraction** with the μ-formula to be 32·06–33·81, and with the μ^2-formula 15·28–16·66. J. E. Calthrop studied the relation between the at. vol., and the index of refraction. K. Spangenberg compared the mol.

refractions of the oxides, sulphides, selenides, and tellurides. M. A. Shirmann studied the polarization of light by submicroscopic particles of tellurium.

R. T. Simmler [6] observed that the **flame spectrum** of tellurium in a colourless gas-flame is continuous, and a similar result was obtained by G. Werther; A. Mitscherlich also observed that the spectrum of the vapour of tellurium in burning hydrogen is continuous. The flame spectrum of tellurium was also examined by G. Salet, W. N. Hartley, and J. M. Eder and E. Valenta. The **spark spectrum** of tellurium between electrodes of that element was observed by W. A. Miller, W. Huggins, R. J. Lang, H. Nagaoka and co-workers, L. and E. Block, A. M. Vieweg and co-workers, J. C. McLennan and A. C. Lewis, and T. R. Robinson. As in the case of sulphur, tellurium furnishes two spectra—the line, and the band spectra. The **line spectrum** of tellurium obtained by the gas discharge between tellurium electrodes was measured by R. Thalén, A. Ditte, G. Salet, R. Capron, G. L. Ciamician, W. N. Hartley, W. N. Hartley and W. F. Adeney, R. J. Lang, E. Demarçay, C. Runge and F. Paschen, A. de Gramont, F. Exner and E. Haschek, P. Köthner, P. G. Nutting, A. Hagenbach and H. Konen, E. Goldstein, and J. M. Eder and E. Valenta. The principal lines in the visible region are 6438 in the red, 6040·7, 6011·3, 5974, and 5936 in the orange-yellow; 5982, and 5756 in the yellow; 5707, and 5648 in the yellowish-green; 5575, 5489, 5478, 5448, 5367, 5311, 5218, 5153, and 5105 in the green; 4302, 4275, and 4260 in the indigo-blue; and 4221, 4062, 4055, 4006, 3984, and 3969 in the violet. W. L. Dudley and E. V. Jones found that the spark spectrum remained the same after the element had been fractionally precipitated by hydrazine hydrochloride twenty times. E. J. Allin studied the under-water spark spectrum. The **arc spectrum** was examined by F. Exner and E. Haschek, A. Hagenbach and H. Konen, H. S. Uhler and R. A. Patterson, M. Kimura, J. Stark and R. Küch, E. Gehrcke and O. von Baeyer, and J. M. Eder and E. Valenta. The **band spectrum** was obtained by G. Salet by passing a spark through the vapour of tellurium. D. Gernez obtained an **absorption spectrum,** extending from the yellow to the violet, by passing light through the vapour of tellurium in an atm. of carbon dioxide. The absorption spectrum was studied by A. W. Wright, J. J. Dobbie and A. J. Fox, J. C. McLennan and R. F. B. Cooley, B. Rosen, A. Michaelis, R. V. Zumstein, E. Rütten, C. H. Cartwright, and W. Friederichs; and the band spectrum, by R. Mecke. F. K. Bell examined the ultra-red absorption spectrum of organic sulphur compounds. The **reflection spectrum** was examined by J. Trowbridge and W. C. Sabine; the **cathode ray spectrum,** by P. Lewis; the **emission spectrum** of the vapour by E. Paterno and A. Mazzucchelli; and the resonance spectrum, by B. Rosen, who gave $\gamma=\alpha-250{\cdot}4n+0{\cdot}53n^2$, where α=23930, 25451 and 22411 respectively for the exciting mercury lines 4359 A., 4046 A., and 5461 A. The **ultra-violet spectrum** is particularly rich in lines. It was observed by F. Exner and E. Haschek, A. Grünwald, R. J. Lang, P. Lacroute, R. V. Zumstein, and V. Schumann. J. C. McLennan and co-workers, H. Schüler and H. Brück, E. V. Condon and G. H. Shortley, A. Porzeborsky, and R. C. Gibbs and A. M. Vieweg discussed the **structure** of the arc spectrum. R. J. Lang discussed the **series spectrum.**

According to W. Steubing,[7] the vapours of the four elements of the sulphur family show a marked **fluorescence** discussed in connection with selenium, and similarly also with the observations of D. Diestelmeier, H. R. Pogorzelska, and B. Rosen; J. C. McLennan and co-workers studied the fluorescence spectrum of tellurium vapour. H. R. Pogorzelska examined the banded fluorescence of the resonance spectrum of tellurium vapour. W. Steubing found that a magnetic field has no effect on the intensity of the resonance and fluorescent spectra. W. Kessel also studied the resonance spectrum; and A. Smekal, the **Raman effect.**

The K-series in the **X-ray spectrum** of tellurium was observed by F. C. Blake and W. Duane,[8] A. Leide, S. Björck, B. Walter, B. B. Ray, M. Siegbahn, K. Chamberlain and G. A. Lindsay, M. Siegbahn and E. Jönsson, and there occur the lines $0{\cdot}456\alpha,\alpha$; and $0{\cdot}404\beta,\beta$. The L-series was measured by D. Coster, Y. Nishina, A. Leide, B. B. Ray, E. Hjalmar, K. Chamberlain and G. A. Lindsay, S. Björck,

M. Lindsay, M. Siegbahn, and H. Hirata. They include $3{\cdot}29100\alpha_2\alpha^1$; $3{\cdot}28199\alpha\alpha$; $3{\cdot}06997\beta\beta$; $2{\cdot}877\beta_2\gamma$; $2{\cdot}70647\gamma_2\delta$; $3{\cdot}04004\beta_4\gamma$; and $3{\cdot}00133\beta_3\phi$. S. Björck, and Y. Nishina also measured the M-, N-, and O-series. W. Herz gave $2{\cdot}43\times10^{-12}$ for the **vibration frequency.**

H. Müller[9] observed that the exposure of tellurium to intense α-rays did not affect the induced **radioactivity.** N. Piltschikoff studied the Moser rays emitted by tellurium; and T. Pavolini, and R. S. Bartlett, the **photoelectric effect** of tellurium films. E. Rupp studied the absorption of slow electrons by tellurium. B. Rosen discussed the resonance potentials. G. Piccardi calculated 8·43 volts for the **ionization potential.** E. Rabinowitsch and E. Thilo studied the subject. J. Vrede found that tellurium is not a good **radio-detector.**

A. de la Rive[10] noticed that tellurium is electrified by rubbing it with wool; and P. E. Shaw and C. S. Jex said that the triboelectricity acquired with glass is negative. K. F. Herzfeld discussed the metallic conductivity of tellurium. P. W. Bridgman said that the electrical properties of tellurium are unusual and variable; it is seldom that two observers obtain the same numerical values for any of its properties. This is taken to mean that tellurium under ordinary conditions contains two modifications in unstable equilibrium, and the proportions of the two forms change greatly with the manner of treatment—thus, the temp. coeff. of the same piece may be positive or negative according to its treatment. A. Matthiessen said that the **electrical conductivity** is such that if silver at 0° be 100, that of tellurium is 0·000777 at 19·6°. This works out at about 0·000466 mho at 19·6° (silver 60×10^{-4}), or roughly an **electrical resistance** of 2000 ohms. P. W. Bridgman gave for the sp. resistance of simple crystals at 20°, 56,000 ohms when parallel and 154,000 ohms when vertical to the chief axis. A. Matthiessen and M. von Bose added that when heated, the resistance increases with temp. up to 70°–80°. A. Schulze gave 2·1 for the ratio of the resistance in the solid and liquid state; A. Günther-Schulze made some observations on this subject. F. Exner said that at 20° the conductivity is 0·00293 if the element has been rapidly cooled, and, if slowly cooled, 0·00437. He found that the resistance R, arbitrary units, of a rod was:

	20°	50°	101°	180°	290°	182°	100°	51°	22°
R . .	7·07	7·86	8·10	5·25	4·40	5·21	14·75	31·1	40·0

The detailed results are plotted in Fig. 4. The resistance increases as the temp. rises to about 140°, and then falls up to 200°; as the temp. falls from 200°, the resistance increases steadily so that at ordinary temp. it is nine times as great as it was at 200°, and four to six times as great as it was initially at ordinary temp. On repeating the experiment the maximum no longer appears, but the resistance steadily decreases from the lowest to the highest temp. The more rapidly the sample is cooled, the smaller the final resistance, and conversely. The explanation is attributed to the better development of the crystals with slow cooling. E. Matthey found the resistance of a sample of 97 per cent. tellurium to be about 800 times as great as that of copper. For the ratio of the resistance R at $\theta°$ and R_2 at 0°, H. K. Onnes and B. Beckman found a minimum at −225°:

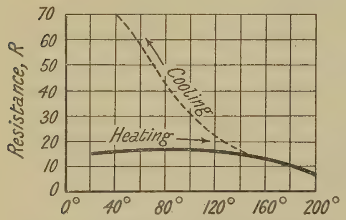

FIG. 4.—The Electrical Resistance of Tellurium (Heating and Cooling).

	−80°	−100°	−140°	−180°	−220°	−225°	−240°	−258·6°
R/R_0 .	0·773	0·732	0·659	0·596	0·547	0·546	0·568	0·624

H. Perlitz studied the relation between the space-lattice and the change of resistance with fusion; and R. Schuhmann found no difference in the e.m.f. of cells with amorphous and crystalline tellurium. V. Lenher and J. L. R. Morgan, A. Matthiessen, F. W. Warburton, F. Exner, W. G. Adams, and A. Guntz and W. Broniewsky, showed that the *structure* has a great influence on the resistance; they found that the sp. resistance of tellurium varied from 279 to 1152 ohms. A. Guntz and W. Broniewsky found that the sp. resistance of tellurium at 2° is 0·102 ohm, and, increasing with temp., attains a maximum at about 50°. It then diminishes until the m.p. is reached, Fig. 5; and added that, in agreement with F. Exner, the abnormal variation is due to the separation of crystals of varying sizes, and not to the formation of an allotropic modification of tellurium as was supposed by E. Cohen and J. F. Kröner. For J. M. Riviere's observations, *vide infra*, silver telluride. B. Beckman found the sp. resistance varied from 0·0493 to 0·617 ohm per cm. cube, and the *pressure* coeff. varied linearly from $-9\cdot1\times10^{-5}$ to $-26\cdot6\times10^{-5}$. P. W. Bridgman obtained a resistance of 0·00645 ohm per cm. cube; and a press. coeff. of —0·00012; and the average temp. coeff. from 0° to 24° was —0·0063. W. G. Adams said that the conductivity of tellurium is slightly increased by *exposure to light*, but not to the same extent as that of selenium. T. W. Case found that tellurium has a resistance less than a megohm, and does not change its resistance on exposure to light. R. S. Bartlett observed that tellurium shows a photoelectric effect at ordinary temp., and a 70 per cent. greater effect at —185°. P. Kapitza studied the change of the resistance in a magnetic field. L. Amaduzzi and M. Padoa found that isomorphous mixtures of selenium and tellurium show photoelectric sensibilities—ratio of the conductivity in darkness and in light—such that with 0·887 to 10·081 at. per cent. Te, the curve falls rapidly at first and then slowly with increasing tellurium content.

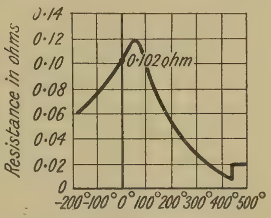

Fig. 5.—The Variation of the Electrical Resistance of Tellurium with Temperature.

C. A. Kraus and E. W. Johnson gave for the sp. resistance, R, of tellurium:

	480·5°	466·0°	449·1°	431·8°	404·7°	380·5°	363°
$R\times10^3$.	0·488	0·525	0·579	0·663	11·69	13·31	14·81
	Liquid				Solid		

and for the resistance at 440° of mixtures of tellurium and sulphur:

S .	0·0	5·0	30·0	50·0	70·0	75·0	77·5	80·0	85·0 per cent.
R .	$0\cdot0_36410$	$0\cdot0_38910$	0·2390	15·71	1870	10,920	33·650	114,500	231,700

B. Lange and W. Heller studied the **thermoelectric force** of the tellurium-platinum couple between —75° and 90°, and found that the thermoelectric force is almost constant, but it increases linearly from 0° to 40°, and nearly linearly up to 400°. A. Teichmann also measured the thermoelectric force of this couple. W. Ogawa also found the e.m.f. of the thermocouple with copper and tellurium to be -1000μ volts, and the current passes from tellurium to the copper at the hot junction.

M. A. Levitsky and M. A. Lukomsky found that the bismuth-tellurium couple gives a current of 360 microvolts per degree or three times that of the iron-constantan couple.

A. von Ettinghausen observed the change in the resistance of tellurium when exposed to a *magnetic field*; C. W. Heaps found that for small magnetic fields, of strength H, the effect on the resistance, R is $dR/R=100\cdot0\times10^{-12}H^2$ for transverse fields, and $dR/R=27\cdot7\times10^{-12}H^2$ for longitudinal fields. The subject was studied by P. Kapitza. According to P. I. Wold, the change of resistance in the magnetic field is proportional to the square of the field strength. The resistance of tellurium was very variable at ordinary temp., depending on the previous heat-treatment, but diminished with rise of temp. and in all cases approximated to the same value at 150° C. The increment in resistance in the magnetic field was greater at the lower temp., the curve connecting change of resistance and temp. being very similar to that for resistance and temp.

The **Hall effect** in tellurium is abnormally large (sixty times greater than in bismuth), so that if there is any close connection between the Hall effect and the change of resistance in a magnetic field one would expect the curve for the latter phenomenon to exhibit abnormal properties. The relatively large values of dR/R in tellurium, however, are small compared with those of dR/R in bismuth. P. I. Wold, and F. W. Warburton studied the Hall effect with tellurium. P. I. Wold found the Hall effect is practically independent of the field strength—up to 15,000 c.g.s. units. There is a disymmetry with reversal of field, but since this is proportional to the square of the field it is due to the Hall electrodes not being exactly on an equipotential. At ordinary temp. the Hall constant is positive, but it diminishes rapidly with rise of temp., changes sign, and with further rise of temp. reverses to positive again. The initial value depends on the heat-treatment, but there is always the double reversal as the temp. rises. It is only at ordinary temp. that widely different values of the constant are obtained ; at higher temp. the curves for different heat treatments approach each other, and the reversal to the second positive value occurs at 245° C. This behaviour cannot be regarded as due to impurities, special precautions having been taken in preparation of the specimen, and analysis showed the amount of oxide present to be exceedingly small. The author considers it due to the existence of two crystalline forms, α and β. According to W. Haken, the α modification is stable below 354° C. and the β form above this temp. The author assumes a positive Hall constant for the β modification and a negative for the α. As the Te is cooled the β form passes into the α form, but the quantity making the transition will vary. A curve connecting thermoelectric power and temp. has a shape similar to that for Hall constant and temp. Measurements of the Hall constant for liquid tellurium were unsatisfactory. The Hall effect has not been observed with amorphous substances—excluding gases—and it seems as if a crystalline structure is necessary for the Hall effect. The Ettinghausen-effect was found to be proportional to the field strength and to increase with rise of temp. The Nernst-effect was also approximately proportional to the field, but diminished in value with increase of mean temp. of the plate. The Leduc-effect was proportional to the field strength. A diminution of about 19 per cent. in the thermal conductivity was observed in a field of 6500 c.g.s., the mean temp. of the plate being 45·3° C. G. Polvani observed a lag with respect to the magnetic field of the Hall effect.

Observations on the electrolysis of dil. soln. of potassium hydroxide with tellurium electrodes were made by J. W. Ritter,[11] H. Davy, H. G. Magnus, J. C. Poggendorff, C. Himly, and G. Bredig and F. Haber—at the platinum anode, there is an evolution of oxygen, but no hydrogen is given off at the cathode. The tellurium passes into soln. as violet potassium telluride, and then is precipitated by the anodic oxygen. The observations of E. Müller, and R. Lucas are indicated above in connection with colloidal tellurium. E. Müller and R. Nowakowsky added that in 0·1N-KOH, selenium dissolves at the cathode with the valency 0·67 to 0·75, sulphur with the valency 0·57 to 0·89, and tellurium dissolves with valency about 0·9. The potentials at which soln. begins (measured against the 0·1N calomel electrode) are sulphur 0·53 volt, selenium 0·804 volt, tellurium 0·07 volt. M. le Blanc observed that tellurium as cathode readily dissolves in alkaline soln., but the dust observed by E. Müller, and R. Lucas is not obtained with very conc. soln. of potassium hydroxide. M. le Blanc found that tellurium in N-KOH dissolves both as anode and cathode. At the cathode it yields a red soln. of polytelluride. At the anode it dissolves with a valency of nearly four, in the form of $Te^{\cdot\cdot\cdot\cdot}$-ions the greater part of which react with hydroxyl ions, forming TeO_3''-ions. Tellurium is insoluble in a normal soln. of potassium hydroxide from which oxygen is excluded. In a 10N-soln., however, it dissolves at 100° to a red soln., from which it separates again on cooling or dilution. This points to the simultaneous presence of positive and negative tellurium ions. A red soln. prepared by cathodic soln. of tellurium, and containing only negative ions, is permanent. No tellurium dissolves when an alternating current is passed between tellurium electrodes in N-potassium hydroxide soln., but in $10N$-soln. dissolution takes place, the quantity dissolved increasing as the number of alternations per minute decreases. Red soln. are formed from which tellurium soon begins to separate. The observations are most simply explained by supposing that tellurium dissolves at the cathode in the form of Te''-ions and at the anode as $\text{Te}^{\cdot\cdot\cdot}$-ions. Equilibrium exists in soln. between these ions and free tellurium, $3\text{Te} \rightleftharpoons 2\text{Te}'' + \text{Te}^{\cdot\cdot\cdot\cdot}$. In very conc. alkaline soln., the equilibrium requires the presence of measurable quantities of the substances on the right-hand side of the equation, but in dil. soln. it is displaced almost entirely towards the left-hand side of the equation. According to E. Müller, the cathodic decomposition potential of tellurous acid in $2N$-sulphuric acid is —0·08 volt. No deposition potential could be obtained for tellurium from a $2N$-sulphuric acid soln. of telluric acid, from which it follows that tellurium cannot be deposited from telluric acid. According to L. Schucht, with dil. soln. of tellurous acid, tellurium is deposited loosely on the anode; and with a conc. soln. the separated tellurium floats in the liquid. E. Müller also observed that when faintly alkaline soln. of sodium tellurite or tellurate are electrolyzed there is a marked reduction to tellurium which is not hindered by the presence of chromates. According to J. Lukas and A. Jilek, a bright, adherent deposit of tellurium with a silvery lustre can be obtained by dissolving say 3 grms. of a tellurium compound in 3 c.c. of hot, conc. sulphuric acid. The cold soln. is diluted with water and 0·5 grm. of tartaric acid added, followed by ammonia until neutral to methyl-red; the soln. is acidified with 3 grms. of malonic acid, cooled to 18°, treated with 10 grms. of ammonium sulphate diluted to 120–150 c.c. and electrolyzed with a rotating anode in a platinum dish at 2 volts. The current, originally 0·03–0·09 amp., falls to 0·004–0·007 amp. when the tellurium is completely deposited. Without shutting off the current, the deposit is washed first with water, then with alcohol, dried at 100°, and weighed; it should possess a bright, silvery lustre and be firmly adherent to the dish. Tellurium is amphoteric, for, when used as cathode in the electrolysis of potassium hydroxide, J. Kasarnowsky found that it dissolves as a univalent element forming potassium telluride, K_2Te_2, but when used as anode in the electrolysis of hydrochloric acid, the tellurium passes into soln. as a quadrivalent metal forming tellurium tetrachloride. The normal potential of the system Te/Te_2'' in potassium hydroxide soln. is —0·818 volt; and with the system $\text{Te}/\text{Te}^{\cdot\cdot\cdot\cdot}$, 0·549 volt. The thermal value for the system: $3\text{Te} \rightleftharpoons \text{Te}^{\cdot\cdot\cdot\cdot} + 2\text{Te}$ is 136 Cals.; of $5\text{Te} \rightleftharpoons \text{Te}^{\cdot\cdot\cdot\cdot} + 2\text{Te}_2''$ is —129 Cals.; and $\text{Te} + \text{Te}'' = \text{Te}_2''$ is 3·5 Cals. Tellurium as a metal comes between copper and silver in the **electrochemical series,** and it is the "noblest" of the metalloids. The hypothetical system $\text{Te} \mid N\text{-Te}^{\cdot\cdot\cdot\cdot}, N\text{-Te}_2'' \mid \text{Te}$ should have an ionic product $[\text{Te}^{\cdot\cdot\cdot\cdot}][\text{Te}_2'']^2 = 10^{-95}$, which gives a measure of the amount of ionization into positive and negative ions. F. W. Bergstrom found that in liquid ammonia the electrochemical series is Pb, Bi, Sn, Sb, As, P, Te, Se, S, and I. W. Haken observed a discontinuity in the thermoelectric properties at 354° due, he supposed, to the existence of two allotropes.

H. Euler observed that the cell $\text{Te} \mid \text{sat. soln. } H_2TeO_4, N\text{-KCl} \mid \text{HgCl}$ gave no **potential difference,** but with other specimens of tellurium higher and lower values were obtained; and with the cell $\text{Te} \mid \text{TeCl}_2, N\text{-KCl} \mid \text{HgCl}$, 0·19 volt was observed by R. Lorenz and J. Egli. G. C. Schmidt in studying the passivity of metals found that there is so small a change of potential on polishing tellurium as to be scarcely detectable. G. Gallo obtained 127·61 for the **electro-chemical equivalent** of tellurium, and added that it generally goes into soln. as quadrivalent tellurium, but with N-HCl, or 10 per cent. potassium chloride, potassium nitrate, or sodium pyrophosphate and hydrochloric acid, it goes into soln. as sexivalent tellurium, never as bivalent tellurium. D. Reichinstein found for the electrode potential $\text{Te}^{\cdot\cdot\cdot\cdot} \rightarrow \text{Te}$, 0·558 volt; for $\text{Te} \rightarrow \text{Te}_2''$, —0·827; and the e.m.f. of the cell

$\mathrm{Te} \mid \mathrm{Te}^{\cdot\cdot\cdot\cdot}, \mathrm{Te}_2'' \mid \mathrm{Te}$ is 1·385 volt. The solubility product $[\mathrm{Te}^{\cdot\cdot\cdot\cdot}][\mathrm{Te}_2'']^2 = 6{\cdot}2 \times 10^{-97}$; and the constant $K = [\mathrm{Te}^{\cdot\cdot\cdot\cdot}][\mathrm{OH}']^6/[\mathrm{TeO}'']$ is 2×10^{-47}. R. Schumann found that the e.m.f. of the cell $\mathrm{Te}_{\mathrm{solid}}\mathrm{TeO}_{2\mathrm{solid}} \mid 0{\cdot}10$ to $0{\cdot}74N\text{-}\mathrm{HClO}_4 \mid \mathrm{H}_2$(1 atm.) is —0·5286 volt at 25°, and —0·5213 volt at 45°. The **reduction potential** for $\mathrm{Te}_{\mathrm{solid}} + 2\mathrm{H}_2\mathrm{O} = \mathrm{TeO(OH)}^{\cdot} + 3\mathrm{H}^{\cdot} + 4(-)$ is —0·5509 volt. J. Kasarnowsky gave —0·91 volt for the normal potential $\mathrm{Te}_2'' \rightarrow \mathrm{Te}_{\mathrm{metal}}$. F. Joliot measured the deposition potential of tellurium. A. C. Krueger and L. Kahlenberg, and S. J. French and L. Kahlenberg studied tellurium-gas cells where the gas is oxygen, hydrogen, helium, argon, or nitrogen.

E. T. Wherry[12] found tellurium to be a poor radio-detector. W. Ogawa, and I. Stransky discussed the rectifying action of tellurides. A. Günther-Schulze described the cathodic spluttering of tellurium.

The diamagnetism of tellurium was observed by J. C. Poggendorff,[13] F. Zantedeschi, and A. Oppenheim. J. Königsberger found the **magnetic susceptibility** to be $-2{\cdot}1 \times 10^{-6}$ vol. unit; S. Meyer, $-0{\cdot}6 \times 10^{-6}$ vol. unit at 18°; and A. von Ettinghausen, $-1{\cdot}6 \times 10^{-6}$ vol. unit. P. Curie gave $-0{\cdot}3 \times 10^{-6}$ mass unit between 20° and 305°; G. Wistrand, $-1{\cdot}70 \times 10^{-6}$ mass unit; P. Curie, $-0{\cdot}303 \times 10^{-3}$ mass unit; J. C. McLennan and E. Cohen, $0{\cdot}308 \times 10^{-6}$ mass unit; K. Honda, $-0{\cdot}32 \times 10^{-6}$ mass unit between 18° and 440°; and for the molten element above 440°, $-0{\cdot}04 \times 10^{-6}$ mass unit. A. Dauvillier discussed the diamagnetism and at. structure of tellurium. P. Pascal gave -378×10^{-7} for the **atomic susceptibility**; and S. S. Bhatnagar and C. L. Dhawan, $-40{\cdot}5 \times 10^{-6}$.

§ 4. The Chemical Reactions of Tellurium

In agreement with the general observation that the basic properties of the natural families of elements increase with rising atomic weight tellurium exhibits a greater basicity than selenium and sulphur. Sulphur is decidedly an acidic element, the acid character is weaker with selenium, and weaker still with tellurium. The last-named element exhibits feeble basic qualities since it forms a tartrate, basic sulphite and basic nitrate, and in this respect it exhibits the characters of a metal. Tellurium also resembles metal in general appearances. Lord Rayleigh and W. Ramsay,[1] and F. Fischer and F. Schrötter were unable to form a compound of **argon** and tellurium. According to H. Davy, F. Becker, J. Löwe, E. Priwoznik, F. Jones, M. G. Weber, and B. Brauner when tellurium is distilled in **hydrogen** a little tellurium hydride is formed; but A. Gutbier said that this is not the case with purified tellurium. A. Ditte observed that tellurium hydride is formed if tellurium be heated with hydrogen in a sealed tube. J. J. Berzelius said that crystalline tellurium does not change in **air,** but precipitated tellurium, when dried in air, is slightly oxidized, while B. Brauner, M. Berthelot and C. Fabre, and A. Gutbier found that a slight oxidation occurs during the washing of precipitated tellurium; and tellurium can be detected in the runnings from the filter; if allowed to stand exposed to air in the presence of hydrochloric acid, much tellurium tetrachloride passes into soln. J. J. Berzelius said that tellurium, heated in air somewhat above its m.p., burns with a bright blue flame which is green at the edges. The flame is attended by a white cloud of the oxide, which, according to J. J. Berzelius, and H. G. Magnus, has a faint unpleasant odour different from that of selenium; the horse-radish oxide reported by M. H. Klaproth is attributed to the presence of admixed selenium. H. B. Baker and H. B. Dixon observed that tellurium is one of the few elements which will burn in thoroughly dried **oxygen.** A. Mailfert said that in the presence of water **ozone** oxidizes tellurium to telluric acid. C. F. Cross and A. F. Higgin said that **water** does not act on tellurium either at ordinary temp. or when heated in a sealed tube at 160°. H. V. Regnault also found that tellurium does not decompose water at a red-heat. L. J. Thénard observed that **hydrogen dioxide** does not act on tellurium; but A. Gutbier and F. Resenscheck found that a soln. of the element in potash-lye is oxidized to tellurate. G. Schluck found that colloidal tellurium is acted on by very dil. soln. of the dioxide, whilst the crystalline modification only reacts slowly with 60 per cent. hydrogen dioxide at 100°. The rate of dissolution increases with the amount of telluric acid formed. Amorphous tellurium, precipitated from hydrochloric acid soln. by sulphur dioxide and dried at 105°, behaves similarly to crystalline tellurium, but if the amorphous variety is dried by treatment with alcohol and ether, it dissolves quite readily in conc. hydrogen dioxide soln. P. Köthner observed that an aq. soln. of **sodium dioxide** converts tellurium into the trioxide which dissolves as tellurate.

H. Moissan found that **fluorine** reacts with tellurium with incandescence forming a crystalline fluoride. H. Davy said that tellurium burns to the tetrachloride in **chlorine.** H. Rose found that chlorine does not attack powdered crystalline tellurium in the cold; but when feebly warmed, a reaction sets in with incandescence forming tellurium di- or tetrachloride according as the tellurium or the chlorine is in excess. On the other hand, J. Thomsen said that chlorine reacts slowly with tellurium at ordinary temp., and if a little sulphur be present, the reaction is faster. C. Willgerodt studied tellurium as a catalyst—*chlorüberträger*—in the chlorination of organic compounds. J. J. Berzelius found that **bromine** reacts with tellurium at ordinary temp., with the disengagement of heat, forming a bromide; tellurium and **iodine** can be melted together in any proportions; and if a mixture is heated strongly enough tellurium iodide sublimes. O. Ruff and H. Krug showed that tellurium reacts with incandescence with **chlorine fluoride.** W. Engelhardt observed that colloidal tellurium readily reacts with a soln. of iodine and potassium iodide. J. Thomsen said that **hydrochloric acid** is without action on tellurium. According to V. Lenher, although tellurium is ordinarily considered to be insoluble in hydrochloric acid, yet it is actually attacked slightly by the acid when exposed to the air, if sufficient time is allowed for contact. This action can be demonstrated by bubbling a current of air, for several weeks, through conc. hydrochloric acid in which is suspended metallic tellurium. In a comparatively short time the acid becomes yellow, indicating the presence of tetrachloride.

J. J. Berzelius said that **sulphur** can be melted with tellurium in all proportions—*vide infra*, tellurium sulphide. R. Weber, and E. Divers and M. Shimose observed that dry **sulphur dioxide** reacts with tellurium at 30° forming red tellurium sulphotrioxide. F. J. Müller von Reichenstein, and M. H. Klaproth, N. W. Fischer, H. G. Magnus, and H. Rose, and E. Divers and M. Shimose found that conc. or fuming **sulphuric acid** dissolves tellurium at ordinary temp. forming a red soln.; and, according to N. W. Fischer, with the conc. acid, sulphur dioxide is evolved. Tellurium separates out when water is added to the soln., and when heated, sulphur dioxide is evolved. The colour of the soln., said R. Weber, is probably due to the formation of tellurium sulphotrioxide. M. G. Levi and co-workers found that a soln. of potassium persulphate dissolves tellurium; E. Moles found that tellurium reacts with sulphuric acid giving a soln. with an increased conductivity, and hence mol. wt. determinations are ambiguous. According to R. Auerbach, tellurium in accord with its metallic character dissolves in **pyrosulphuric acid** as monatomic molecules, and in coagulation, the colour changes from red, through violet, to blue—*cf.* selenium oxysulphates. J. Thomsen said that tellurium vigorously decomposes **sulphur monochloride** forming tellurium tetrachloride; and this was shown by V. Lenher to occur when the monochloride is in excess, while F. Krafft and O. Steiner found that the dichloride is produced if the tellurium be in excess. W. Prandtl and P. Borinsky said that selenium or tellurium forms with **chlorosulphuric acid** an unstable soln. containing, respectively, $SeSO_3$ or $TeSO_3$; it reacts with **pyrosulphuryl chloride** to form $TeCl_4.SO_3$, in accord with the equation: $Te+2S_2O_5Cl_2=SO_3.TeCl_4+2SO_2+SO_3$; **chlorosulphonic acid** reacts: $Te+HClSO_3=HCl+TeSO_3$; and **sulphuryl chloride** is without action in the cold but forms the tetrachloride when heated, while B. von Horvath said that purified tellurium reacts at ordinary temp., and at a red-heat forms tellurium tetrachloride and sulphur dioxide; **thionyl chloride** yields the same products together with sulphur. V. Lenher also studied the action of sulphuryl and thionyl chlorides on tellurium. L. Tschugaeff and W. Chlopin found that in an atm. free from oxygen tellurium dissolves in sodium hydroxide containing **sodium hyposulphite** forming sodium telluride. J. J. Berzelius observed that **selenium** and tellurium can be melted together in all proportions, and heat is at the same time evolved—*vide supra*. C. A. Cameron and J. Macallan found that **selenic acid** dissolves tellurium in the cold forming a red soln. which is decomposed by water with the separation of tellurium; the red substance is probably tellurium selenotrioxide.

G. Gore, E. C. Franklin and C. A. Kraus, and C. Hugot found that tellurium is unchanged by liquid **ammonia.** F. W. Bergstrom found that tellurium reacts fairly quickly with the **amides** of potassium and sodium at ordinary temp., and slowly at −33°. C. A. Kraus discussed the complex anions formed by tellurium in ammonia soln. C. C. Palit and N. R. Dhar observed that 13 and 26 per cent. **nitric acid** exert but a slight action on tellurium in 3 hrs. According to A. Oppenheim, when a mixture of **phosphorus** and powdered tellurium is warmed, part of the tellurium forms a black compound, and part burns to phosphorus oxide. V. Lenher observed that **phosphorus trichloride,** and **phosphoryl trichloride** are without action on tellurium. J. J. Berzelius, and A. Oppenheim said that tellurium and **arsenic** can be melted together in all proportions; and similarly with **antimony** or **bismuth.** F. Jones found that **arsine** is converted by tellurium into arsenic telluride and hydrogen telluride; and **stibine** behaves in an analogous manner. J. Hoffmann observed no characteristic coloration is produced by tellurium in molten **borax;** the tellurium is sparingly dissolved, and forms a regulus. On the other hand, sodium telluride colours the molten borax brown or black. Molten **boric acid** dissolves some telluride and when cold the mass is brown; with fused **microcosmic salt,** and sodium telluride, a reddish-brown glass is formed, which, on the addition of boric oxide, becomes amber-yellow. P. Fenaroli found that, as in the case of selenium, the oxidized element does not colour **glass,** but if reducing conditions are present blue, brown, and red glasses are produced. Some contain colloidal soln. of the element, and others, polytellurides. The former correspond completely with the tellurium hydrosols, and are, like them, of two fundamental colours, blue and brown, analogous to the red selenium glass. The blue glass contains larger colloidal particles than the brown. The glass containing polytellurides is red, or violet-red, and has an absorption spectrum which corresponds exactly with that of aq. soln. of polytellurides, showing an absorption from the green to the violet, with a distinct maximum between 480 and 490$\mu\mu$.

J. W. Retgers found that tellurium is not dissolved by **benzene,** or **xylene;** and with **methylene iodide** it forms a dark brown soln.—100 parts of the solvent dissolve 0·1 part of tellurium at 12°. W. Muthmann said that the methylene iodide dissolves tellurium only when the liquid contains a little free iodine, but this was contradicted by J. W. Retgers. A. Gutbier added that tellurium decomposes the methylene iodide and passes into soln. as tellurium iodide. A. Oppenheim's observations on the action of a soln. of **potassium cyanide** have been discussed in connection with the separation of this element from selenium and sulphur. V. Lenher observed that **carbon tetrachloride** does not react with tellurium; and K. Lindner and L. Apolant found that when tellurium is heated with **carbonyl chloride,** tellurium dichloride is formed. H. Wayts and G. Cosyno studied the action of tellurium on organo-magnesium compounds. A. C. Vournasos found that when heated with **sodium formate,** tellurium hydride is formed. J. Dean studied some organic compounds of tellurium.

The action of tellurium on the **metals** is indicated in connection with the tellurides. According to M. le Blanc, when tellurium is heated with a N-soln. of **potassium hydroxide,** while protected from air, no action occurs at ordinary temp. or at 100°; but with a 10N-soln., the liquid becomes blood-red and the dissolved tellurium is precipitated when the soln. is diluted. H. Rose observed the formation of tellurides when tellurium is melted with alkali hydroxide; and J. J. Berzelius observed a similar result with **alkali carbonate.** M. Websky said that when tellurium is fused with **potassium hydrosulphate,** tellurium dioxide, or potassium tellurite is formed; and F. Becker found that fused **potassium nitrate** forms alkali tellurate; and similarly also with a fused mixture of potassium hydroxide and chlorate—*vide* the tellurates. Tellurium acts as a reducing agent on many salts of the heavy metals. Thus, J. B. Senderens obtained a partial reduction of **copper sulphate or acetate,** and he represented the reaction of powdered tellurium with **silver nitrate** at 100° by $4AgNO_3+3Te+3H_2O=2Ag_2Te+H_2TeO_3+4HNO_3$. In sealed tubes, the precipitation of the silver by tellurium is always complete, and if the tellurium is in excess, the nitric acid which is formed is decomposed with production of nitrogen peroxide even in dil. soln. Silver nitrate in soln. is completely although slowly reduced by selenium and tellurium at the ordinary temp. R. D. Hall and V. Lenher, and F. Hundeshagen, represented the action on **gold chloride** by $4AuCl_3+3Te=3TeCl_4+4Au$. Selenium reduced a soln. of gold chloride only when boiled; so that tellurium is a more active reducing agent than selenium. R. Böttger found that **ferric salts**—sulphate, ferrocyanide, etc.—are reduced to ferrous salts. F. W. Bergstrom found that tellurium failed to react with magnesium, arsenic, or copper in liquid ammonia, but did dissolve very slowly in soln. of aluminium and potassium cyanides. Evaporation of these soln. to dryness appeared to cause decomposition into cyanide and elementary tellurium. No definite compounds were isolated. Arsenic failed to react with soln. of potassium or aluminium cyanides over a long period of time. E. Kessler, and A. Gutbier and co-workers studied the purple substance, analogous to purple of Cassins, produced by the deposition of tellurium on **stannic hydroxide**—that is, *tellurium-tin purple.* H. Lessheim and co-workers discussed the co-ordination number of tellurium in its complex salts.

Some reactions of analytical interest.—As in the case of selenium, tellurium forms two acids—tellurous and telluric acids. When a soln. of a tellurite is treated with **hydrochloric acid,** a white precipitate of tellurous acid, H_2TeO_3, may be formed

89448

in conc. soln.; with a soln. of a tellurate, there is no precipitation, but if the soln. be boiled, chlorine is evolved, and when water is added, tellurous acid may be precipitated. Acidic soln. of a tellurite yield a brown precipitate of tellurium sulphide, TeS_2, when treated with **hydrogen sulphide,** and the precipitate is soluble in ammonium sulphide soln.; under similar conditions the tellurates behave like the tellurites to which they are reduced. As previously indicated—*vide* Figs. 1 and 2 of the previous chapter—**sulphur dioxide** precipitates tellurium completely from dil. hydrochloric acid soln., and this even in the presence of tartaric acid; but with a conc. hydrochloric acid soln., unlike selenious acid, no tellurium is precipitated even on boiling. Tellurous and telluric acids give similar products when treated with reducing agents—**stannous chloride** precipitates black tellurium if the soln. be not too acid; **zinc** gives a similar precipitate; **phosphorous acid** precipitates tellurium from conc. soln., but not from cold, dil. soln.; and **ferrous sulphate** gives no precipitate with tellurous or telluric acids although with the selenium acids precipitation occurs.

According to P. Jannasch,[2] an ammoniacal soln. of **hydroxylamine** reduces tellurous and telluric acids causing the complete precipitation of the tellurium, whilst an acidic soln. of this reagent is without action on these acids; hydroxylamine may therefore be employed in separating selenium and tellurium. The selenium is completely precipitated when a hydrochloric acid soln. of these elements is boiled with hydroxylamine, and the tellurium separates quantitatively when the filtrate is rendered ammoniacal and boiled with more of the reducing agent; four mols. of hydroxylamine are required for the reduction of one mol. of tellurous acid, water and nitrogen being produced at the same time. Tellurium is also precipitated from its hydrochloric acid soln. by **hydrazine sulphate,** but not from its soln. in nitric acid; hydrazine precipitates tellurium quantitatively from a hot ammoniacal soln. G. Pellini said that a feebly acidic soln. of selenium containing ammonium tartrate gives a precipitate with hydrazine sulphate, but not so with tellurium; hydrazine chloride precipitates both selenium and tellurium. For the action of other reducing agents—*vide infra*, tellurous and telluric acid. With magnesia mixture, tellurites give a white precipitate; so also with sodium hypophosphate, and with barium chloride. G. Denigès [3] found that a soln. of 10 grms. of **mercurous nitrate** in 10 c.c. of nitric acid and 100 c.c. of water gives a yellow crystalline precipitate with telluric acid or tellurates. If a tellurium compound or tellurium be melted with **potassium cyanide** in a current of hydrogen, potassium telluride is formed. When the cold mass is dissolved in water, and a current of air passed through the soln., unlike the case with selenium, the element itself is precipitated.

The physiological action of tellurium.—Soln. of the tellurium salts have a metallic taste; and, according to K. Hansen,[4] and A. P. A. Rabuteau, they are poisonous. B. Turina found that like selenium salts, tellurium—as tellurite or tellurate—does not enter the system of germinating or mature plants in appreciable quantities by way of the root-hairs; rather does the root-sap play the important rôle of point of entry and filtration for nutrifying salts. F. Czapek and J. Weil said that in the organism tellurium salts are rapidly reduced to the metallic state, which is harmless. F. Wöhler, K. Hansen, F. Mylius, and J. L. Beyer were of the opinion that a small quantity of telluric or tellurous acid—say, 1 mgrm.—taken internally is reduced to tellurium simultaneously forming a volatile compound—possibly methyl telluride—which imparts to the breath a most offensive odour. F. Lehmann said that high concentrations of tellurium salts are fatal to trypanosomes, but after one hour's exposure, the following dilutions were not lethal: tellurites 1 : 500; and tellurates 1 : 300. G. Joachimoglu and W. Hirose observed that on an isolated frog's heart, sodium tellurite is at least two hundred times as toxic as sodium tellurate, and sodium selenite at least one hundred times as toxic as sodium selenate. The selenite is also much more toxic than the tellurite. The heart muscalature has a reducing effect on the first three salts mentioned.

On the rabbit's blood-press., sodium selenite and tellurite have a more powerful depressor action than sodium selenate and tellurate. They also showed that diphtheria bacilli are less sensitive than the bacilli of the typhus-coli group towards tellurites and tellurates. The former are killed by conc. of tellurites 1 : 420, and tellurates 1 : 125—while the latter are killed at dilutions 400 times these amounts. According to A. Massen, the solid compounds of selenium and tellurium are attacked by *Penicillium brevicaule*, forming volatile substances. The volatile selenium compound has a mercaptan-like odour, quite distinct from that of the arsenic compound, but cultures containing tellurium emit an odour resembling that of garlic. Whilst in the animal organism selenium and tellurium compounds are converted into ethyl derivatives, in microbes, methyl derivatives are formed. The reducing property of the cells of animals and microbes is due to the presence of a substance which can exercise this power even when removed from the tissues, but the formation of methyl or ethyl derivatives seems, however, to be really dependent on vital processes occurring only in the organism. O. Rosenheim, and A. Massen discussed the effects of the presence of selenium and tellurium on the biological tests for arsenic. B. Gosio added that whilst all arsenical compounds are attacked only by a comparatively few species of hyphomycetes; only some of tellurium compounds are attacked by all the varieties of hyphomycetes tried. The action with the tellurium compounds is more rapid than with arsenical compounds, and under favourable conditions can be detected in 2 or 3 min. It is said to be probable that the decomposition of tellurium compounds by micro-organisms is not brought about by means of products formed by the organisms, but is a direct consequence of the life or development of the moulds or bacteria. B. Gosio, and E. Scheurlen recommended the use of tellurium compounds as tests for bacterial life in substances supposed to have been sterilized. L. D. Mead and W. J. Gies found that non-toxic doses of tellurium (as oxide, tellurite, tartrate, and tellurate) do not materially affect metabolism in dogs. They appear to stimulate katabolism, and diminish fat absorption slightly; the urine is rendered dark brown. Large doses retard digestion, and induce vomiting and somnolence. They cause enteritis. Subcutaneously injected, they cause diarrhœa, tremors, and death from asphyxia. At the point of injection, tellurium is deposited in the metallic form, and is distributed in most of the organs and tissues. Methyl telluride appears in the breath a few minutes after the introduction of quite small amounts of tellurium into the system. It persists for months, slowly leaving the body, by skin, lungs, urine, bile, and fæces. Of the digestive ferments, trypsin is the least resistive to the destructive influence of the metal. Albumin and bile pigment are usually present in the urine. T. Bokorny said that a 0·1 per cent. aq. soln. of telluric acid, or of potassium tellurite or tellurate, has no action on various algæ and infusoria. W. Adolphi described a case of poisoning from the fumes of tellurous oxide volatilized during the smelting of some platinum slimes. N. M. Stover and B. S. Hopkins found that sodium or potassium tellurite, or tellurium acid tartrate in 0·0005N- to 0·05N-soln., exert no perceptible fungicidal action.

Some uses of tellurium compounds.—On account of some industrial applications, tellurium is beginning to acquire some technical importance.[5] It has a very limited application in the glass industry; it is used in the preparation of organic dye-stuffs; in the manufacture of electrical equipment; high resistance alloys and ultramarine; in the colouring of lithophone; the staining of silver; as a delicate test of sterilization in bacteriology; and as a toning agent in photography. A compound of tellurium has been used as an anti-knock constituent of motor fuels, and its use is said to lead to greater efficiency. Remarkable properties are shown by the alloys of tellurium; the tin alloys are extremely hard and have very great tensile strength; and the aluminium alloys are very ductile. The silver alloys have been used. The element is poisonous, and is fairly readily absorbed—*e.g.* from gold dental stoppings. F. C. Mathers and J. Papish used soln. of salts of tellurium for staining metals; C. Dickens used colloidal tellurium as an insecticide, germicide, fungicide, and wood preservative.

§ 5. The Atomic Weight and Valency of Tellurium

> Le tellure a donc subi toutes les tortures auxquelles un corps peut être soumis. Il a été fondu, sublimé, oxyde, hydrogéné, dissous et précipité, mais, le nombre 125, représentant le poids atomique de tellure pur, inscrit dans son tableau périodique par Mendeléeff, n'a été, jusqu'ici, confirmé par personne.—G. N. WYROUBOFF.

Tellurium shows a clear and definite relationship to selenium and to sulphur. This is evidenced by the valencies as shown by corresponding compounds. Thus, tellurium is bivalent in tellurium dichloride, $TeCl_2$, hydrogen telluride, H_2Te, the organic tellurides—*e.g.* ethyl telluride, $(C_2H_5)_2Te$, prepared by A. Marquardt and A. Michaelis[1]—and the inorganic tellurides—*e.g.* Ag_2Te, etc. According to F. Becker, and A. Cahours the organic tellurides form additive compounds with the alkyl iodides yielding the so-called *telluronium salts*—*e.g.* triethyl telluronium iodide, $(C_2H_5)_3TeI$, in which the tellurium is quadrivalent. There are also compounds like diethyl tellurium oxide, $(C_2H_5)_2TeO$, and the salts $(C_2H_5)_2TeCl_2$, etc., in which the tellurium is also quadrivalent. According to G. Pellini, $(C_6H_5)_2TeBr_2$ is isomorphous with the corresponding selenium compound $(C_6H_5)_2SeBr_2$. According to T. M. Lowry, the tetrahedral configuration of the sulphur and selenium does not apply to tellurium since R. H. Vernon has isolated two stereoisomeric forms of E. A. Demarçay's dimethyl telluronium diiodide:

$\begin{matrix}CH_3\\CH_3\end{matrix}>Te<\begin{matrix}I\\I\end{matrix}$

and

$\begin{matrix}CH_3\\I\end{matrix}>Te<\begin{matrix}CH_3\\I\end{matrix}$

The isomerism is best explained on the assumption that the four valencies of tellurium lie in one plane. In these compounds, two of the valencies of tellurium appear to be different from the other two, whereas with sulphur and selenium, one valency appears to be different from the other three. Hence, the same argument which indicates that the four radicles of isopropylidene iodide

$\begin{matrix}CH_3\\CH_3\end{matrix}>C<\begin{matrix}I\\I\end{matrix}$

are not coplanar shows that the four radicles in the analogous compounds of tellurium have a square not a tetrahedral configuration. The subject was discussed by R. F. Goldstein, and by T. M. Lowry and co-workers. The quadrivalency of tellurium is also illustrated by tellurium tetrachloride, $TeCl_4$, which, according to A. Michaelis, has a normal vap. density, and passes into tellurous acid, $TeO(OH)_2$, when treated with water. The sexivalency of tellurium is represented by the hexafluoride, TeF_6, prepared by E. B. R. Prideaux, but not so clearly in telluric acid, known only in the form of the dihydrate, $H_2TeO_4.2H_2O$, which may be orthotelluric acid, $Te(OH)_6$, and in the tellurates which have a formal resemblance to the selenates and sulphates. The isomorphism of these salts has been previously discussed. I. I. Tschernyeff discussed the constitution of the complex salts; and J. N. Frers, the place of tellurium in the periodic table.

According to the periodic law, tellurium should have an at. wt. between that of antimony and iodine—that is, it should be greater than 120, and less than 126. J. J. Berzelius[2] gave 128 for the at. wt. of tellurium, while iodine has an at. wt. very near to 126·5. D. I. Mendeléeff accepted 125 for the at. wt. based, he said, on the work of B. Brauner; but this value for the at. wt. of tellurium is too low; all the best determinations agree that the at. wt. of tellurium is above that of iodine. This means that either all the observations are affected by a constant error, or else the theory is insufficient to describe the facts.

B. Brauner said that tellurium is not a simple substance, because on distilling tellurium in a current of hydrogen, or the tetrabromide, in vacuo, it can be separated into two constituents, one more volatile than the other, and having a different at. wt. He added that as a result of fractional precipitation with ammonia, tellurium as ordinarily understood is probably a mixture of three elements, and that pure, red tellurium remains to be discovered. P. E. Browning and R. Flint also said that if purified tellurium tetrachloride be partially hydrolyzed by water, and the precipitated tellurium dioxide separated by filtration the tellurium has an at. wt. of 126·53 ; whereas the tellurium salt remaining in soln., when precipitated by ammonia and a slight excess of acetic acid, contains tellurium which has an at. wt. of 128·97. They called the former *α-tellurium*, and the latter β-tellurium. These results were subsequently confirmed by R. Flint. G. Pellini suggested that tellurium contains a small quantity of an element of at. wt. 212, apparently corresponding with D. I. Mendeléeff's *di-tellurium*, Dt, which B. Brauner called *austriacum*, and which is said to be analogous to the radioactive constituents of pitchblende. W. Grünewald said that his spectroscopic observations on tellurium agree with the assumption that a dwi-tellurium was present. E. W. Wetherell asked :

> May it not be possible that the atoms of an element may in some cases have a satellite —a minute body inseparable from the atom by any means at our disposal, yet one which may materially affect the properties of an element ? Such satellite would in no way upset the law of Avogadro that equal vols. of a gas under equal press. and temp. contain equal numbers of molecules, as the satellite is an integral part of the molecule ; it might even account for the very slight deviation from the law which has been observed.

These speculations and observations have not been supported by others, and this in spite of a bias, so to speak, in favour of the heterogeneity of tellurium. A. G. V. Harcourt and H. B. Baker attributed the results by P. E. Browning and R. Flint to the failure of the methods of purification to remove some element of lower eq. wt. than tellurium, and that this impurity accumulated by the process of fractionation employed. A. G. V. Harcourt and H. B. Baker were unable to confirm R. Flint's results. W. G. Morgan, and G. Pellini obtained results in agreement with those of A. G. V. Harcourt and H. B. Baker, and opposed to those of R. Flint. W. Marckwald believed that by a laborious fractional crystallization of telluric acid, he obtained tellurium of lower at. wt. than that of iodine, but on repeating the work by a more trustworthy process, W. Marckwald and A. Foizik concluded that no separation of the tellurium had been effected. L. Staudenmaier fractionally crystallized telluric acid ; J. F. Norris and co-workers fractionally crystallized potassium bromotellurate ; J. F. Norris fractionally distilled tellurium dioxide ; H. B. Baker and A. H. Bennett fractionally crystallized telluric acid, fractionally dissolved barium tellurate, and fractionally distilled the metal, the chloride, and the dioxide, fractionally decomposed the hydride, fractionally precipitated the chloride, and fractionally electrolyzed the bromide and the chloride ; V. Lenher fractionally precipitated the tetrachloride or complex chlorides ; fractionally precipitated the tetrachloride with ferrous salts, and fractionally dissolved tellurium in hydrochloric acid in the presence of air. W. L. Dudley and P. C. Bowers fractionally precipitated tellurium by a hydrazine salt ; O. Steiner, and G. Pellini fractionally distilled phenyl telluride ; and G. Pellini fractionally hydrolyzed the tetrachloride, and fractionally electrolyzed a soln. of tellurium dioxide in sulphuric acid and ammonium hydrotartrate. In all cases, these investigators were unable to distinguish any difference in the at. wts. of the different fractions, and they concluded that tellurium is chemically homogeneous ; *i.e.* if tellurium is a mixture the components cannot be separated by the processes so far investigated. The differences observed by W. Bettel in the cupellation of silver telluride ores were attributed by H. B. Baker to differences in the surface tensions of silver telluride and silver ; and have no bearing on the controversy on the complexity of tellurium —*vide infra*, isotopes.

J. J. Berzelius [3] made the first attempt to determine the at. wt. of tellurium by oxidizing the element to the dioxide by means of nitric acid, and from the ratio

Te : TeO_2, he calculated 128·34 for the at. wt. when his data are reduced to oxygen 16 as the standard. W. L. Wills also obtained results ranging from 126·64 to 129·66 ; and a whole series of observations on the oxidation of tellurium to the dioxide, or the reduction of the dioxide to tellurium have been made. Thus, for the oxidation, B. Brauner obtained 125·72, and for the reduction, 127·46 ; G. Pellini obtained for the oxidation 127·657, and for the reduction, 127·625 ; G. Gallo found 127·053 ; V. Lenher, 127·50 ; A. Gutbier, 127·585, 127·609, and 126·74 ; L. Staudenmaier, 127·60 ; R. Metzner, 128·032 ; K. B. Heberlein, 127·002 ; L. M. Dennis and R. P. Anderson, 127·61 ; A. Stähler and B. Tesch, 127·513 ; and P. Bruylants and C. Desmet, 127·75. J. B. A. Dumas by an unpublished method obtained 129 for the at. wt. of tellurium.

C. von Hauer analyzed potassium bromotellurate, and from the ratio $K_2TeBr_6 : 6AgBr$, obtained 127·64 ; W. L. Wills from the same ratio obtained 127·10. B. Brauner obtained from the ratio TeBr : 4Ag, 127·64 ; M. Chikashige, 127·42 ; H. B. Baker and A. H. Bennett obtained from the ratio Te : $TeBr_4$, 127·53 (Br=74·92). W. L. Dudley and P. C. Bowers precipitated tellurium by a hydrazine salt and from the ratio $TeBr_4$: Te, calculated 127·479. V. Lenher obtained 127·57 from the ratio $K_2TeBr_6 : 2KCl$. L. Staudenmaier obtained 127·16 from the ratio $H_6TeO_6 : TeO_2$, and 127·31 from the ratio H_6TeO_6 : Te ; W. Marckwald gave 126·81 ; and K. B. Heberlein similarly obtained 126·72. H. B. Baker objected to telluric acid as a starting point because of the difficulty in obtaining the acid with exactly the right proportion of water of crystallization, $H_2TeO_4.2H_2O$. K. B. Heberlein treated telluric acid with hydrochloric acid, collected the liberated chlorine in potassium iodide, and titrated the freed iodine with standard thiosulphate ; he thus obtained Te=127·223. O. Steiner analyzed phenyl telluride, and from the ratio $(C_6H_5)_2Te : 12CO_2$ obtained Te=126·42 ; A. Scott from the ratio $(CH_3)_3TeI : AgI$ obtained 127·56 ; and from the ratio $(CH_3)_3TeBr : Ag$, 127·72. J. F. Norris ignited the basic nitrate, and from the ratio $Te_2HNO_7 : 2TeO_2$ obtained 127·48. W. L. Dudley and P. C. Bowers showed that the basic nitrate method is not so reliable owing to variations in composition with variations in the nature of the precipitate. H. B. Baker and A. H. Bennett heated tellurium dioxide with sulphur, and from the ratio $TeO_2 : SO_2$, obtained 127·62. W. Marckwald and A. Foizik said that the results by this process are not so good owing to the formation of a little sulphur trioxide. F. A. Gooch and J. Howland oxidized an alkaline soln. of tellurium dioxide to telluric acid by adding an excess of a standard soln. of permanganate, and after acidification with sulphuric acid, titrated back the excess with oxalic acid. They thus obtained 126·92 for the at. wt. of tellurium ; J. F. Norris and H. Fay determined the excess of permanganate iodometrically. W. Marckwald and A. Foizik also oxidized the tellurium dioxide to telluric acid by permanganate in an acidic or an alkaline soln. The results gave 127·61 for the at. wt. of tellurium. P. Bruylants and J. Michielsen calculated 127·8 from the ratio Te : H_2 in hydrogen telluride. G. Gallo found the electrochemical equivalent of tellurium in terms of silver, and he found that if the at. wt. of silver be 107·880, that of tellurium is 127·053.

The available data were reviewed by K. Seubert, and P. Köthner in 1903 ; and by F. W. Clarke in 1910. F. W. Clarke gave 127·5 as the best representative value for the at. wt. ; and the International Table for 1926, 127·5, and for iodine, 126·92. Tellurium is therefore considered to be a misfit in the periodic table of at. wts. As G. N. Wyrouboff,[4] and H. Wilde expressed it, the law of periodicity ceases to be valid. J. W. Retgers accordingly argued that tellurium should be placed in the eighth group, and he said, in support of this, that potassium tellurate and osmiate are isomorphous. On the other hand, W. Muthmann said that the general character of tellurium ; the isomorphism of potassium selenium bromide, and potassium tellurium chloride ; and the isomorphism of the trigonal forms of tellurium and selenium make tellurium fitted for a place in the periodic table along with sulphur and selenium. As indicated above, J. W. Retgers considered that the cases of isomorphism cited by W. Muthmann are open to doubt. In spite of this, the chemical characters alone, in the opinion of K. Seubert, make tellurium a member of the sulphur-selenium family; and, added A. Gutbier and F. Flury, the anomaly would not be avoided by placing tellurium in the eighth group away from its congeners sulphur and tellurium in the sixth group. A. Werner showed that the anomaly exhibited by tellurium is itself periodic and appears in other parts of the table—*e.g.* with argon (39·9) and potassium (39·15); with cobalt (59·0) and nickel (58·7); and with neodymium (143·6) and praseodymium (140·5). P. Kusnetzoff pointed out that when the differences in the at. wts. of the elements in the uneven periods are tabulated, they show a regular rise and fall within the separate groups. The negative difference between iodine and tellurium is in accord with the other differences in the sixth group.

The case of tellurium shows that the position of an element in the periodic table is not entirely dependent on its at. wt., but on some other property of the atom to which the at. wt. is nearly proportional. A. van den Broek [5] showed that if the elements are arranged in the order of their at. wts. they are in nearly all cases also arranged in the order of increasing nuclear charge; and it is the nuclear charge not the at. wt. which should determine the position of the element in the periodic table; and H. G. J. Moseley showed that the variation in the wave-length of the characteristic X-rays emitted by different elements can be explained on the assumption that the nuclear charge increases by one unit from element to element. The nuclear charge is represented by so-called **atomic number,** which for tellurium is 52.

The theory of isotopes has also changed the point of view of the at. wt. question. According to F. W. Aston,[6] the mass spectrum of tellurium gives lines corresponding with **isotopes** of the at. wts. 126, 128, and 130, the intensities of the latter two being equal and double that of the first. All the mass numbers of tellurium probably form members of isobaric pairs. H. Pettersson and G. Kirsch [7] observed evidence of **atomic disruption** when tellurium is bombarded by α-rays. H. Müller obtained no evidence of this. A. L. Foley studied the action of ultra-violet light; and of X-rays on tellurium confined in sealed glass tubes when the spectra are periodically examined. The results were indefinite. The **electronic structure** according to N. Bohr is (2) (4, 4) (6, 6, 6) (6, 6, 6) (4, 2). The subject was discussed by M. L. Huggins, G. I. Pokrowsky, C. P. Smyth, H. G. Grimm and A. Sommerfeld, J. D. M. Smith, J. C. Slater, and C. D. Niven.

Polonium is discussed in connection with radium.

§ 6. Hydrogen Telluride

J. W. Ritter[1] observed that when water is electrolyzed with a tellurium cathode, no hydrogen is evolved on the metal, but the liquid is coloured owing, he supposed, to the formation of a tellurium hydride ; H. Davy also found that, under similar circumstances, the water about the cathode acquires a purple tint owing to the formation of hydrogen telluride. If air be present, a brown powder is precipitated which he regarded as a tellurium hydride containing a smaller quantity of hydrogen. On the other hand, H. G. Magnus showed that the brown powder is nothing but metallic tellurium, and it is precipitated even when thoroughly boiled water is employed because of the diffusion of cathodic oxygen into the liquid. If the water be acidified, no brown powder is deposited because the hydrogen telluride which is then produced, being but slightly soluble in the acid liquor, escapes as a gas. Gaseous **hydrogen telluride,** H_2Te, was discovered by H. Davy.

H. Davy observed that when the telluride—obtained by electrolyzing potassium hydroxide by means of a tellurium cathode ; or by heating potassium and tellurium together—is treated with dil. hydrochloric acid, there is a violent effervescence, and an aëriform compound of tellurium and hydrogen is produced which smells very like hydrogen sulphide, and which gives elemental tellurium when it comes in contact with air. As indicated previously, H. Davy, F. Becker, J. Löwe, E. Priwoznik, F. Jones, B. Brauner, A. Ditte, and A. Gutbier discussed the direct union of hydrogen with heated tellurium. M. G. Weber obtained only traces of the telluride to be formed by the direct union of the two elements. E. Pozzi-Escot observed only a very slight hydrogenation of tellurium occurs during diastatic fermentation. Hydrogen telluride is produced by the action of acids on tellurides—*e.g.* H. Davy, and A. Bineau used potassium telluride ; J. J. Berzelius, zinc or iron telluride ; and M. Berthelot and C. Fabre, magnesium telluride. M. G. Weber obtained only a poor yield by the action of an acid on magnesium telluride ; and E. Ernyei, a gas with only 5 per cent. of hydrogen telluride. F. Wöhler, L. M. Dennis and R. P. Anderson, and R. de Forcrand and H. Fonzes-Diacon found that water acting on aluminium telluride furnishes hydrogen telluride ; E. Divers and M. Shimose acted on zinc with a soln. of tellurium dioxide in sulphuric acid. J. C. Poggendorff obtained hydrogen telluride by the electrolysis of dil. sulphuric acid with a tellurium cathode. A. C. Vournasos observed the formation of hydrogen telluride when tellurium is heated with sodium formate to 400°. The yield is limited because of the reverse reaction—the decomposition of the telluride. In all these cases, the product is contaminated with much hydrogen. By the electrolysis of 50 per cent. sulphuric acid, in an apparatus resembling Fig. 6, E. Ernyei obtained a gas containing only 5 to 6 per cent. of hydrogen. M. G. Weber also obtained the best yield by the electrolytic process. E. Ernyei's apparatus is as follows :

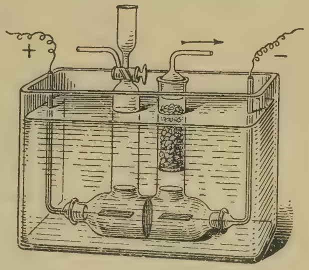

Fig. 6.—The Preparation of Hydrogen Telluride.

> The negative pole is of tellurium ; the electrolyte of 50 per cent. sulphuric acid is cooled during the electrolysis between −15° and −20°. The electrolytic cell has a diaphragm, Fig. 6, of parchment paper to retard movements of the electrolyte. Two glass tubes rise from this cell—the one over the positive pole is fitted with a two-way cork, funnel and bent tube. The latter is to introduce liquid into the cell, and the former is to allow air to be washed from the apparatus by a current of hydrogen before the electrolyte is introduced, and afterwards for the exit of the anode gases. The tube over the negative pole has a partition above which calcium chloride and phosphorus pentoxide can be placed for drying the gas. The fittings are all of glass since cork and rubber decompose the gas. W. Hempel and M. G. Weber cooled the vessel with solid carbon dioxide and alcohol ; and protected the apparatus from light.

L. M. Dennis and R. P. Anderson prepared the gas by the electrolysis of a 50 per cent. soln. of phosphoric acid using a tellurium cathode and platinum anode. The hydrogen telluride was purified by liquefaction, and fractional distillation a number of times. P. Bruylants and J. Michielsen purified the gas from the electrolysis of sulphuric acid in a similar way, and employed it in their determinations of the at. wt. of tellurium. L. Moser and K. Ertl said that the best way of preparing the gas is to drop powdered aluminium telluride into dil. hydrochloric acid in an atm. of nitrogen. The best yield was 80 per cent. of the theoretical. The gas was liquefied in a tube cooled with a mixture of solid carbon dioxide and ether. Liquid hydrogen telluride is sensitive to light, but the dry gas is stable in light. F. Paneth and co-workers observed that hydrogen telluride is formed by an electric discharge with tellurium electrodes in hydrogen.

H. Davy described hydrogen telluride as a colourless gas with a fœtid smell like that of hydrogen sulphide ; and M. Berthelot and C. Fabre said that its odour is different from that of hydrogen sulphide, or selenide, and it slightly resembles that of hydrogen arsenide. Its action on the animal economy is very much less irritating than is that of the selenide. A. Bineau estimated the **vapour density** to be 4·49 (air unity) when the calculated value for H_2Te is 4·48. E. Ernyei determined the vap. density to be 4·49. When the gas is cooled with solid carbon dioxide, it forms lemon-yellow, needle-like crystals with the **melting point** —54° according to E. Ernyei, and —48° according to R. de Forcrand and H. Fonzes-Diacon. The liquid is greenish-yellow, and it has a **specific gravity** of 2·57 at 20°; P. Bruylants gave 2·65 at 0°. E. Rabinowitsch gave 48·9 for the mol. vol. H. Remy discussed the structure of hydrogen telluride. P. Bruylants found the **vapour pressure,** *p* mm., to be

	−60°	−50°	−40°	−30°	−20°	−10°	0°
p . .	36	79	139	234	370	555	808

The **boiling point** is 0° at 760 mm. E. Ernyei said the b.p. is over 0°; E. Q. Adams studied the relation between the b.p. and composition. P. Bruylants gave —1·8°, and he estimated the **critical temperature** to be at about 200°. The **triple point** is at —45·4° and 102 mm.; the latent **heat of vaporization** was estimated to be 5·7 cals. M. Berthelot and C. Fabre found that the **heat of formation** is $(H_{2gas}, Te_{cryst.})=H_2Te_{gas}-35{\cdot}0$ Cals.; and R. de Forcrand gave —50·8 Cals. for the solid telluride. The heat of formation of water, hydrogen sulphide and hydrogen selenide are respectively 59·0, 4·6, and —12·3 Cals.; thus showing that in the oxygen group, as in the chlorine group, the energy of combination with hydrogen diminishes as the at. wt. of the element rises. A 0·1*N*-soln. of hydrogen telluride, in the absence of air, according to L. Bruner, has a sp. **electrical conductivity** of 2×10^{-3}, and at this conc. is 50 per cent. ionized. M. de Hlasko found for the mol. conductivity μ, of soln. of hydrogen telluride at 18°; the sp. conductivity k ohms; the **ionization constant** k, where $k=\alpha^2/(1-\alpha)v$; and α represents the **degree of ionization :**

	0·093*N*-	0·0667*N*-	0·06173*N*-	0·3442*N*-	0·02326*N*-	0·01186*N*-	
μ .	56	63	67	855	107·5	136	208·5
k .	0·00124	0·004215	0·004061	0·002942	0·002497	0·001607	0·000579
K .	0·00240	0·00223	0·00226	0·00222	0·00259	0·00250	0·00180
α .	0·148	0·166	0·176	0·225	0·283	0·360	0·549

The mean value of the ionization constant is $K=0{\cdot}00227$ at 18°. Hydrogen telluride thus appears to be a stronger acid than hydrogen fluoride. The increase in the strength of the hydrogen acids of this family of elements thus increases rapidly with increasing at. wt. Thus, the ionization constants for H_2O is $0{\cdot}64\times10^{-14}$, for H_2S, $0{\cdot}91\times10^{-7}$; H_2Se, $1{\cdot}88\times10^{-4}$; and for H_2Te, $2{\cdot}27\times10^{-3}$. The increasing acidity with increasing at. wt. was also noted by L. Bruner

Hydrogen telluride was found by M. Berthelot and C. Fabre to be very unstable even in darkness. E. Ernyei also found that decomposition occurs in a sealed tube, and it can be kept for a couple of days while cooled by a freezing mixture, but even under 0°, it decomposes into tellurium and hydrogen. A. Ditte said that when warmed, it behaves like hydrogen selenide, but at a much lower temp. He said that it becomes more stable at a somewhat higher temp., but at a still higher temp., a large proportion is decomposed. Both H. Davy, and E. Ernyei found that the gas burns in **air** with a pale blue flame forming water, and tellurium dioxide. According to M. Berthelot and C. Fabre, and R. de Forcrand and H. Fonzes-Diacon the gas is decomposed at once by moist air, and a piece of moist filter-paper in contact with the gas is blackened immediately. The gas dissolves in **water** forming a red soln.—presumably owing to the separation of tellurium. The aq. soln. reddens litmus; water with air in soln. at once decomposes the gas. L. Bruner added that if a bubble of oxygen be allowed to come in contact with the aq. soln. of the gas, the soln. is decomposed, tellurium separates, and the conductivity falls to zero, thus proving that the electrical conductivity of the aq. soln. is really due to the hydrogen telluride. H. Davy found that **chlorine** reacts vigorously with the gas forming tellurium which is quickly converted into chloride; and E. Ernyei observed that an aq. soln. of **bromine** is decolorized by the gas; and similarly also with **iodine.** According to C. Whitehead, **tellurium tetrachloride** reacts with the gas: $2H_2Te+TeCl_4=3Te+4HCl$. C. Whitehead said that the soln. in 95 per cent. **alcohol** is stable in air. A. Bineau observed that when heated with **tin,** all the tellurium is withdrawn, and an equal vol. of hydrogen is produced. Hydrogen telluride was found by H. Davy, and J. J. Berzelius to dissolve in an aq. soln. of **alkali hydroxide.** E. Ernyei added that the soln. with alkali hydroxide are colourless, and they become red on exposure to air; if the soln. contains oxygen, tellurium separates, and this subsequently dissolves forming a red soln. of potassium telluride. Hydrogen telluride reduces **ferric chloride** to ferrous chloride; M. Berthelot and C. Fabre represented the reaction $2FeCl_{3aq.}+H_2Te=Te+2FeCl_{2aq.}+2HCl_{aq.}+58{\cdot}24$ Cals. E. Ernyei also found that the gas reduces **mercuric chloride** to mercurous chloride. A. Brukl studied the action of the gas on metal salt soln.—*vide* the tellurides.

According to E. Divers and M. Shimose, if hydrogen telluride made by the action of zinc and sulphuric acid holding tellurium dioxide in soln. be passed into more of the tellurated sulphuric acid, not diluted with water, a red soln. of tellurium sulphotrioxide is formed: $2H_2Te+TeO_2+3H_2SO_4=5H_2O+3TeSO_3$, and as the passage of the gas continues, the red sulphotrioxide is destroyed, and there is formed a brown insoluble substance which in some parts appears in the form of scaly, black particles with a metallic lustre, and which is thought to be **hydrogen pertelluride.** Its solubility in sulphuric acid, and its appearance is said to indicate that it is not elemental tellurium. It may, however, form a red soln. if treated with sulphuric acid containing tellurium sulphate, or if fresh sulphuric acid be added to the mother-liquor. In this case, the sulphuric acid probably exercises an oxidizing power by containing traces of dissolved oxygen, or oxidizing agents. It redissolves in its own mother-liquor when the mixture is exposed to the air, the dissolution proceeding from the surface of the liquid downwards, evidently a case of atm. oxidation. But it also redissolves slowly when sealed up with its mother-liquor in glass tubes in an atm. of hydrogen, and this dissolution of it is accompanied by reduction of the sulphuric acid; for on opening the tubes, the smell of sulphur dioxide is distinct. This reduction of sulphuric acid further shows that the precipitate is not tellurium, as this substance dissolves without forming sulphur dioxide. The hydrogen of the pertelluride is readily oxidized by air in the presence of sulphuric acid, and more slowly by sulphuric acid alone, with the production of sulphur dioxide.

§ 7. The Tellurides

A. F. Hallimond [1] discussed the isomorphism of the sulphides, selenides, and tellurides. A. Bineau obtained colourless plates of **ammonium hydrotelluride,** $(NH_4)_2HTe$, by bringing ammonia in contact with an excess of hydrogen telluride. E. Wendehorst obtained the colourless salt by passing purified hydrogen selenide into a sat. soln. of ammonia in an atm. of nitrogen, and cooled below 30°.

H. Davy [2] prepared **potassium telluride,** presumably K_2Te, by warming a mixture of the two elements in an atm. of hydrogen; combination occurs with incandescence. C. A. Tibbals also obtained potassium telluride by the direct union of the elements. H. Davy obtained this compound by the electrolysis of molten potassium hydroxide, using tellurium electrodes; if a conc. soln. of potassium hydroxide is similarly treated, the tellurium dissolves forming a red soln. which is rapidly decomposed with the precipitation of tellurium by the oxygen liberated at the anode. J. J. Berzelius, and G. Magnus melted tellurium with potassium hydroxide or carbonate, and boiled tellurium with conc. potash-lye; in both cases some potassium tellurite is formed; but not so if zinc be present since F. and C. Heberlein observed that by boiling oxy-salts of tellurium with conc. potash-lye, and granulated zinc, the liquid becomes red owing to the formation of potassium telluride. This reaction is recommended as a test for tellurium in minerals. J. J. Berzelius, M. Berthelot and C. Fabre, and E. Ernyei obtained potassium telluride by the action of hydrogen telluride on a soln. of potassium hydroxide in the absence of air; A. Oppenheim, by melting tellurium with potassium cyanide; H. Davy, by heating the tellurite or tellurate with carbon, or, according to A. Oppenheim, in hydrogen; and C. Hugot, by the action of a soln. of potassium in liquid ammonia on an excess of tellurium.

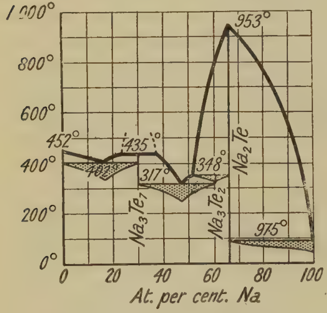

FIG. 7.—Equilibrium Diagram of the System: Na–Te.

M. Berthelot and C. Fabre described their preparation as colourless crystals; E. Demarçay said that the soln. is pale yellow; C. Hugot's preparation was amorphous and white; H. Davy's preparations were copper-red, or steel-grey. M. Berthelot and C. Fabre said that potassium telluride forms a colourless soln. with oxygen-free water. The coloured preparations dissolve in water forming a red liquid. The colour may be due to the presence of a polytelluride, of the monoxide, or of colloidal tellurium. If the strongly alkaline soln. be treated with a reducing agent—say, phosphorus, a hypophosphite, or aluminium—E. Demarçay found that the soln. becomes pale yellow; and similarly, if a soln. of potassium tellurite be treated with a reducing agent, it becomes violet and then yellow. According to M. Berthelot and C. Fabre, and E. Demarçay, the colourless soln. rapidly reddens in contact with air, and, added H. Davy, the red soln. becomes colourless owing to the deposition of the separated tellurium. J. J. Berzelius said that soln. of tellurium in conc. alkali-soln. are decomposed by acids with the evolution of hydrogen telluride. C. A. Tibbals said that the telluride is precipitated in crystals by adding alcohol to a conc. soln. A. Brinkmann did not obtain **lithium telluride** by boiling tellurium with a conc. soln. of lithium hydroxide, or by melting tellurium with lithium hydroxide. G. Pellini and E. Quercigh investigated the sodium tellurides by thermal methods, and the results, summarized in Fig. 7, show that only these compounds which melt unchanged can exist under these conditions, namely, the normal telluride. It is white, and deliquescent; and rapidly darkens on exposure to air. There is also **sodium tritaditelluride,** Na_3Te_2, with a grey metallic appearance; and **sodium tritaheptatelluride,** Na_3Te_7. Neither Na_4Te_3 nor Na_2Te_3 were obtained. H. Davy obtained **sodium telluride,** Na_2Te, by the methods employed for potassium telluride ; likewise also A. Oppenheim, E. Ernyei, and C. A. Tibbals. According to L. A. Tschugaeff and V. G. Chlopin, when tellurium is heated with an alkaline soln. of sodium hyposulphite in the absence of air, tellurium is converted into the unstable sodium telluride, Na_2Te, and sodium sulphide is formed at the same time. The tellurium is probably first transformed by the sodium hydroxide into a mixture of sodium tellurite and telluride, the latter being then converted by the tellurium into polytellurides, which undergo reduction by the sodium hyposulphite: $Na_2S_2O_4+Na_2Te_2+4NaOH=2Na_2SO_3+2Na_2Te+2H_2O$. This reduction is analogous to the action of the hyposulphite on sodium polysulphides. It is possible that the tellurium combines with the sulphoxylate part of the hyposulphite mol., $Na.SO.ONa+Te=Na.Te.SO.ONa$, the unstable compound thus obtained reacting with the sodium hydroxide, thus: $Na.Te.SO.ONa+2NaOH=Na_2Te+O.S(ONa)_2+H_2O$. The formation of the sodium sulphide also obtained in the reaction is probably explained by the equations: $2Na_2S_2O_4+2NaOH=Na_2S_2O_3+2Na_2SO_3+H_2O$, and $Na_2S_2O_3+Na_2S_2O_4+4NaOH=Na_2S+3Na_2SO_3+2H_2O$. The extreme instability of sodium hyposulphite makes it difficult to prepare sodium telluride in large quantities in the above manner. A good yield may, however, be obtained by heating, in a current of hydrogen, a mixture of a gram of tellurium, 6 grms. of sodium formaldehyde-sulphoxylate (rongalite), and 40 c.c. of a 10 per cent. sodium hydroxide soln.: $HO.CH_2.O.SONa+Te+3NaOH=CH_2O+Na_2Te+Na_2SO_3+H_2O$. Sodium telluride is instantaneously decomposed in the air, with separation of tellurium. D. M. Liddell said that if kept from air, sodium telluride is the colour of potassium permanganate, but in air it is decomposed setting free tellurium with the formation of potassium hydroxide. Contrary to G. Pellini and E. Quercigh, C. A. Kraus and S. W. Glass find that sodium telluride and tellurium are miscible in all proportions. The equilibrium diagram is shown in Fig. 8. In addition to the normal telluride, Na_2Te, there are formed the ditelluride with a transition point at 355°, and the hexatelluride with a congruent m.p. at 436°. There are eutectics at 319° with 43 at. per cent. of Na, and at 402·5° with 12·5 at. per cent. Na.

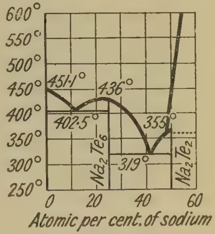

Fig. 8.—The Equilibrium Diagram of Sodium Telluride and Tellurium.

According to C. A. Kraus and C. Y. Chiu, the initial compound formed in the reaction between sodium and tellurium in liquid ammonia is the normal telluride, Na_2Te, which is in equilibrium with **sodium ditelluride,** Na_2Te_2. Figs. 7 and 8 show the range of stability of the compound. C. A. Kraus and S. W. Glass found that it has a transition point at 355°. Its electrical resistance is given in Figs. 9 and 10. The soln. in equilibrium with free tellurium has a composition which varies as a function of the concentration, and the maximum conc. of tellurium corresponds with **sodium tetratelluride,** Na_2Te_4. C. A. Kraus and E. H. Zeitfuchs discussed the mol. wt. of the sodium-tellurium complex formed in liquid ammonia. Tellurides of the heavy metals are formed by double decomposition between sodium telluride and aq. soln. of salts of the heavy metals. C. A. Kraus and S. W. Glass observed the formation of **sodium hexatelluride,** Na_2Te_6, and its equilibrium conditions are illustrated in Fig. 8. It melts at 436° ; and its electrical resistance is indicated in Figs. 9 and 10. C. A. Tibbals said that sodium telluride forms small colourless crystals with much water of crystallization ; and that tellurium dissolves in an aq. soln. of this salt forming **sodium tetritatritelluride,** Na_4Te_3. Tellurium does not dissolve in a soln. of sodium telluride beyond the proportion 4 : 3, and when this soln. is concentrated by evaporation, it breaks down into the normal telluride and tellurium. According to C. Hugot, **sodium hemitritelluride,** Na_2Te_3, is produced by the action of a soln. of sodium in liquid ammonia on an excess of tellurium ; and similarly also with **potassium hemitritelluride,** K_2Te_3. The latter furnishes a violet liquid which becomes brown and viscid at −25°, and when stirred, freezes to a solid. This melts at −15°, and as the ammonia evaporates, at ordinary temp., there remains the hemitritelluride as a dark brown crystalline mass; which, under press. absorbs ammonia and becomes liquid. L. A. Tschugaeff and V. G. Chlopin observed that a soln. of sodium telluride reacts with benzyl chloride or phenylbenzyldimethylammonium chloride forming *benzyl telluride*, $Te(C_6H_5.CH_2)_2$.

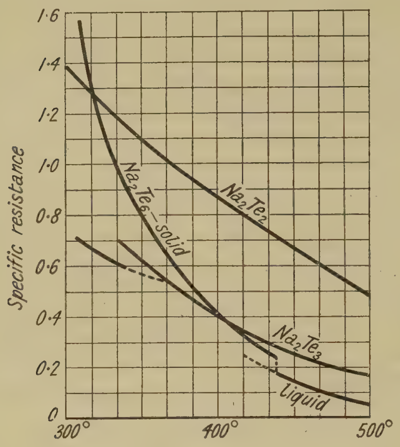

FIG. 9.—The Resistance of the Sodium Tellurides.

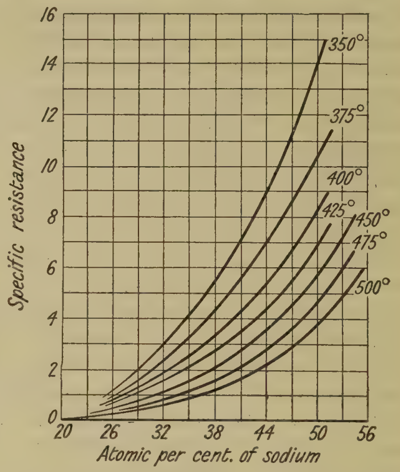

FIG. 10.—The Resistance of the Sodium Tellurides.

J. J. Berzelius[3] prepared a pale red alloy by melting together copper and tellurium; M. Chikashige obtained the alloys by melting mixtures of the two elements in a current of carbon dioxide. T. Parkman said that tellurium precipitates a little copper from cold soln. of copper sulphate or acetate, and likewise also with boiling soln. After boiling tellurium for 4 or 5 hrs. with a soln. of copper acetate, a black powder with the composition of *copper hemitritelluride*, Cu_2Te_3, was formed; and with a boiling soln. of copper sulphate a black powder with the composition of *copper telluride*, CuTe. C. A. Tibbals obtained the monotelluride and also the hemitritelluride by treating a soln. of a copper salt respectively with normal sodium telluride, Na_2Te, and the tetritatritelluride, Na_4Te_3. F. Garelli obtained what appeared to be mixtures of copper tetritatelluride and monotelluride by wrapping a piece of tellurium with copper wire and immersing it in a soln. of copper sulphate. A. Brukl obtained cuprous telluride by the action of sodium telluride on a soln. of sodium cuprous chloride. B. Brauner and B. Kuzma found that in precipitating tellurium by sulphur dioxide from soln. of salts of other metals like copper, some of the metal is precipitated with the tellurium, and this the more the longer the action and the more conc. the soln. W. E. Ford reported a massive mineral which he called **richardite**—after T. A. Richard—occurring in the Good Hope Mine, Vulcan, Colorado. Its composition corresponds with *cuprous telluride*, Cu_4Te_3, or $Cu_2Te.2CuTe$. It has a rich purple colour; sp. gr. 7·54; and hardness 3·5. N. A. Puschin said that this product is a solid soln. of telluride and hemitelluride. E. T. Wherry found richardite to be a poor radiodetector. W. M. Davy and C. M. Farnham observed the behaviour of polished surfaces of the mineral towards etching agents.

According to M. Chikashige, the f.p. curve of the copper-tellurium alloys, Fig. 11, shows a eutectic point at 344° and 17·3 per cent. of copper, and there is a break at 620° with about 34 per cent. of copper; and one at 855°, with 50 per cent. of copper. The break with 50 per cent. of copper corresponds with **copper hemitelluride,** Cu_2Te, which is miscible with copper only to a limited extent—at about 1030°, the hemitelluride dissolves 1 to 2 per cent. of copper, and copper about 4 per cent. of tellurium. From 32·7 to 50 per cent. of copper, the hemitelluride crystallizes primarily in solid soln. with tellurium; and at 623° the mixed crystals with 45 per cent. of copper react with the fused mass to form **copper tetritatritelluride,** Cu_4Te_3, analogous in composition with richardite. A. Mazzucchelli and A. Vercillo obtained a substance of this composition by the action of copper on tellurium tetrachloride, but they regarded it as a mixture of TeCu and $TeCu_2$. According to M. Chikashige, the tetritatritelluride has a transition point at 365° marked by a considerable development of heat. B. Brauner prepared the monotelluride by passing the vapour of tellurium in a current of carbon dioxide over heated copper; and J. Margottet, by heating a mixture of tellurium and copper to redness in an atm. of nitrogen. M. L. Huggins studied the atomic structure. G. von Hevesy and W. Serth studied the diffusion of silver telluride in copper telluride. M. Chikashige found that the hemitelluride has two transition points at 387° and 351°, and the latter is lowered to 334° by the addition of 5 per cent. of tellurium. A. Beutall obtained hair-copper by heating the telluride in a sealed tube at 350°–600°. C. Fabre gave 7·15 Cals. for the heat of formation, and added that the alloy is not stable in air. B. Brauner added that the crystals are rhombohedral, and when heated for a long time they are decomposed with the separation of copper. W. P. Crawford described a massive, bluish-black mineral in the tellurium deposits of Colorado. He called it **weissite**—after L. Weiss; its composition corresponds with **copper pentitatritelluride,** Cu_5Te_3. Its sp. gr. is about 6, and its hardness 3. It gives a violet colour with warm, conc. sulphuric acid. The *weissite* of W. P. Crawford is probably richardite.

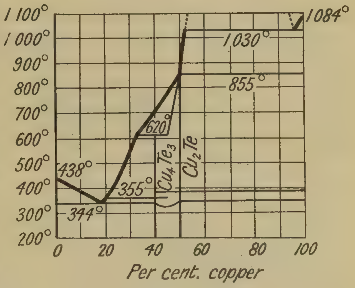

FIG. 11.—Freezing-point Curve of Copper-Tellurium Alloys.

According to N. A. Puschin, the alloys rich in copper are dark grey, brittle, and crystalline; those with 30 to 33 at. per cent. of tellurium are much darker, and more brittle; the colour then becomes dark violet with about 40 at. per cent. of tellurium; the colour becomes paler as the proportion of tellurium rises to 50 at. per cent., when the colour becomes yellow; with higher proportions of tellurium the colour becomes grey. W. C. Roberts-Austin found that the addition of tellurium reduces the malleability of copper. M. Chikashige said that the re-melting of the alloy does not remove the copper; but P. Köthner found that all the tellurium can be removed by distillation in vacuo. I. Stransky discussed the rectifying action of the heavy metal tellurides; and G. P. Thomson, electron diffraction rings. N. A. Puschin found that the potential of copper in the cell Cu | N-$CuSO_4$ | $CuTe_n$ shows breaks corresponding with Cu_2Te, and CuTe, Fig. 12. According to B. Brauner, the tellurium is not removed by fusion with sulphur and sodium carbonate; or, according to M. Chikashige, by fusion with cuprous oxide. F. W. Hinrichsen and O. Bauer said that the telluride dissolves in a soln. of potassium cyanide forming a polytelluride; and when shaken in air, the reddish-violet soln. becomes colourless owing to the deposition of the tellurium in grey flakes. E. Heyn and O. Bauer found that the soln. in potassium cyanide gives a dark grey precipitate with alcohol and cadmium acetate; and C. Whitehead obtained tellurium by electrolyzing the soln. G. Tammann studied the chemical activity of the alloys.

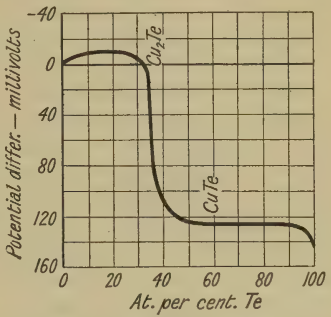

FIG. 12.—Potential Differences of Cu | N-$CuSO_4$ | $CuTe_n$.

The silver tellurides are represented in nature by the three minerals stützite, Ag_4Te; hessite, Ag_2Te; and empressite, AgTe. The mineral **stützite,** probably from Nagyag, Transylvania, was shown by A. Schrauf[4] to have a composition approximating **silver tetritatelluride,** Ag_4Te; and it was named after A. Stütz, who, in 1803, described what appears to have been the same mineral. It is leaden grey, with a reddish tinge. V. Goldschmidt, and C. Hintze regard it as hexagonal or pseudohexagonal with the axial ratio $a:c=1:1{\cdot}2530$; or, as A. Schrauf prefers to regard it, monoclinic with the axial ratios $a:b:c=1{\cdot}73205:1:1{\cdot}24829$, and $\beta=89° 33'$. E. S. Dana emphasized the resemblance to dyscrasite, and chalcocite and said that like them, it may be rhombic. A. des Cloizeaux also regarded stützite as having rhombic symmetry. There is no evidence of the existence of a tetritatelluride on the f.p. curve, Fig. 13. The f.p. curve was first explored, in a preliminary way, by H. Pélabon,[5] who found two eutectics—one at 345° and 34 at. per cent. of silver, and the other at 825° with 78 per cent. of silver—and a maximum representing the normal telluride at 965°. G. Pellini and E. Quercigh made a more detailed study, and their work as revised by M. Chikashige and I. Saito, is illustrated by Fig. 13. Two compounds are indicated on the curve; the normal telluride melting sharply at 957°; and the other **silver heptitatetratelluride,** Ag_7Te_4. The heptitatetratelluride decomposes below its m.p., and exists in two modifications, each of which corresponds with a short branch of the f.p. curve. β-Ag_7Te_4 is formed from Ag_2Te and liquid at 443°; and changes into the α-modification at 403°. Solid soln. are not formed. Eutectics occur at 32 per cent. Ag and 350° and at 87·5 per cent. Ag and 870°, respectively. Annealing experiments indicate that the transformation is one of a single compound, and that a second compound, such as Ag_3Te_2, is not formed. In Fig. 13, the area *A* represents Te+melt; *B*, Te+eutectic E_1; *C*, α-Ag_7Te_4+eutectic E_1; *D*, α-Ag_7Te_4+melt; *E*, β-Ag_7Te_4+melt; *F*, β-Ag_7Te_4+Ag_2Te; *G*, Ag_2Te+melt; *H*, α-Ag_7Te_4+Ag_2Te; *I*, Ag_2Te+melt; *J*, Ag_2Te+eutectic E_2; *K*, Ag+eutectic E_2; *L*, Ag+melt.

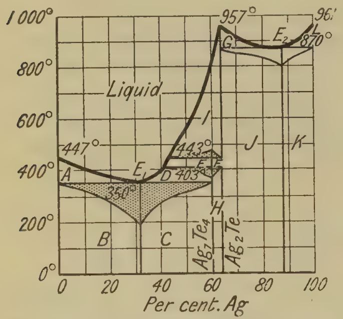

FIG. 13.—Freezing-point Curve of the System: Ag–Te.

The compound which M. Chikashige and I. Saito regarded as hepitatetratelluride was considered by G. Pellini and E. Quercigh to be **silver monotelluride,** AgTe, and they said that its existence is marked by a break in the curve at 444°; and that it undergoes a polymorphic change at 412°. The monotelluride is represented in nature by the mineral **empressite** obtained by W. M. Bradley from the Empress Josephine Mine, Kerber Creek District, Colorado. It occurs in granular and compact masses with a fine conchoidal or uneven fracture, and a pale bronze colour. It is readily soluble in nitric acid. Its hardness is 3·0 to 3·5. E. T. Wherry found empressite to be a poor radio-detector. The mineral was also analyzed by E. J. Dittus; and W. T. Schaller considered it to be a kind of gold-free muthmannite—*vide infra.*

G. Rose[6] described a mineral occurring in the Savodinsky Mine, Zyrianovsky, Altai, Siberia, which he designated *Tellursilber;* J. J. N. Huot, and W. Haidinger called it *savodinskite,* in allusion to its origin; and J. Fröbel, **hessite**—after H. Hess. The term hessite is commonly employed although it has not first claim. A. Schrauf supposed the mineral from Rezbanya, Hungary, to be isomorphous with silver glance and therefore called it *Tellursilberglanz,* and reserved the term *Tellursilberblende* for stützite. Analyses of the mineral have been reported by G. Rose, S. Koch, W. Petz, K. A. Nemadkevich, G. A. Kenngott, F. J. Malaguti and J. Durocher, F. Becke, J. Loczka, C. F. Rammelsberg, G. Küstel, F. A. Genth, F. A. Genth and S. L. Penfield, I. Domeyko, A. des Cloizeaux, F. W. Clarke, A. Carnot, T. L. Walker and A. L. Parsons, E. V. Shannon, and E. S. Simpson. The results agree that hessite is normal silver telluride, *i.e.* **silver hemitelluride,** Ag_2Te, in which gold often replaces part of the silver until the hessite merges into petzite. The occurrence of the mineral in Zyrianovsky, Altai, Siberia, was described by G. Rose, N. von Kokscharoff, and P. von Jeremejeff; in Nagyag, Zalathna, Botes, etc., Transylvania, by P. Groth, G. vom Rath, A. Schrauf, J. A. Krenner, G. A. Kenngott, and F. Becke; in Rezbanya, Hungary, by C. F. Rammelsberg, K. F. Peters, A. Schrauf, and F. von Richthofen; in Kara Issar, Asia Minor, by A. des Cloizeaux; in Karangahake, New Zealand, by J. D. Dana; Kalgoorlie, West Australia, by E. S. Simpson; in Coquimbo, Chili, by I. Domeyko; in Refugio and Quiteria, Mexico, by C. F. de Landero, and F. W. Clarke; in California, Colorado, and Utah, United States, by B. Silliman, W. P. Blake, G. J. Brush, G. Küstel, H. J. Burkart, F. A. Genth, and F. A. Genth and S. L. Penfield.

B. Brauner prepared this telluride by passing the vapour of tellurium over silver at a red-heat. J. Margottet obtained regular octahedra by passing the vapour of tellurium in a current of nitrogen over silver at a dull red-heat. G. Rose, and B. Brauner prepared it by heating a mixture of the two elements. H. Pélabon, G. Pellini and E. Quercigh, and M. Chikashige and I. Saito also obtained it by the direct union of the elements. The conditions of equilibrium are illustrated in Fig. 7. R. D. Hall and V. Lenher obtained this telluride by passing hydrogen telluride into an ammoniacal soln. of silver nitrate, but the black precipitate always contains an excess of silver. C. A. Tibbals, and A. Brukl obtained this telluride as a dark brown or black flocculent precipitate by the action of a soln. of sodium telluride on a soln. of silver acetate in acetic acid; and J. B. Senderens, by the action of tellurium on a soln. of silver nitrate at 100°: $4AgNO_3+3Te+3H_2O=2Ag_2Te+H_2TeO_3+4HNO_3$; the reaction is slow at ordinary temp.—R. D. Hall and V. Lenher represented the reaction $4AgNO_3+3Te=2Ag_2Te+Te(NO_3)_4$. B. Brauner, and R. D. Hall and V. Lenher obtained a product resembling the mineral by passing carbon monoxide or ammonia over silver tellurite heated to a high temp.

The mineral occurs in compact or fine-grained masses—rarely coarse grained. The colour is lead-grey, steel-grey, or iron-black. E. F. Glocker called the yellow earthy telluride *müllerin*, or *Nagyager silver*. The mineral also occurs in crystals more or less modified and often much distorted. According to A. Schrauf, P. Groth, H. Rose, T. L. Walker and A. L. Parsons, J. A. Krenner, C. Palache, V. Rosicky, R. Pilz, and L. Tokody, they are cubic. The distortion led H. Hess, and G. Suckow to assume that the crystals are rhombohedral; G. A. Kenngott, and K. F. Peters, rhombic; and F. Becke, triclinic. According to L. S. Ramsdell, the X-radiogram of hessite indicates that the mineral is pseudo-cubic and probably rhombic. The cubic form is said to represent a high temp. modification. The artificial crystals prepared by J. Margottet were regular octahedra. The cleavage of hessite is indistinct. M. L. Huggins studied the atomic structure of the crystals; and T. Andrews, J. Arnold and J. Jefferson, F. Osmond and W. C. Roberts-Austen, the structure of the alloys. F. A. Genth gave 8·359 for the sp. gr. of varieties free from gold, while G. Rose gave 8·412–8·565. These numbers are probably too high. F. J. Malaguti and J. Durocher, and G. A. Kenngott gave 8·071. W. Petz gave 8·31 to 8·45 for specimens with 0·69 per cent. of gold; F. A. Genth, 8·178. G. Küstel gave 9·0 to 9·4 for a sample with 24·80 per cent. of gold. F. Henglein gave 41·3 for the mol. vol. G. Pellini and E. Quercigh said that the silver tellurium alloys are crystalline, and have a metallic appearance, changing from grey to white as the proportion of silver increases. The brittleness diminishes from tellurium to silver. W. C. Roberts-Austen studied the mechanical properties of these alloys. The hardness of hessite is about 2·5. L. Jordan and co-workers measured the hardness, tensile strength, and elongation of silver-tellurium alloys. G. von Hevesy and W. Serth studied the diffusion of silver in silver ditelluride, and of silver telluride in copper telluride. H. Pélabon gave 955° for the m.p.; G. Pellini and E. Quercigh, 959°; and M. Chikashige and I. Saito, 957°—*vide* Fig. 13.

J. Margottet found that the mineral is partially decomposed at a white-heat; and J. Joly, that hessite sublimes at about 900°. K. Friedrich and A. Leroux said that, unlike silver sulphide, the telluride is not altered by light; and H. E. McKinstry found no effect was produced by exposing the mineral to the electric arc-light. A. Beutell obtained hair-silver by heating the telluride in a heated tube at 350°–600°. A. de Gramont studied the spark spectrum of the mineral. F. Beijerinck described the mineral as an electric conductor. T. W. Case said that the electrical resistance is less than one megohm; and that the conductivity is not affected by exposure to light. R. G. Harvey studied the subject. N. A. Puschin's observations on the potential difference in the cell Ag | $\frac{1}{7}N$-AgNO$_3$ | AgTe$_n$(millivolts) show the existence of only one telluride, Ag$_2$Te. E. T. Wherry called hessite a fair radio-detector. J. M. Rivière's measurements of alloys with 2 (continuous curves) and with 20 (dotted curves) per cent. of silver are summarized. The different curves represent specimens which have been previously heated and at first rapidly cooled to the temp. indicated and then slowly cooled. Below 200°, the resistance is a function of two variables (i) the temp. of measurement; and (ii) the temp. of annealing. For the 12–30 per cent. alloys there is a discontinuity at —20°; and for nearly pure tellurium, one at 415°. J. Margottet observed that when heated to near the m.p. of silver telluride in a current of hydrogen, hair-silver is produced. J. Joly observed that a sublimate is formed between 820° and 930°. C. A. Tibbals observed that the precipitated telluride is quite stable in air, even when moist, and is not acted on by acids other than nitric acid. Hessite also dissolves in hot nitric acid; and when the mineral is heated with conc. sulphuric acid it forms a red or purple liquid which becomes clear when diluted with water, and tellurium is precipitated. W. M. Davy and C. M. Farnham studied the etching of polished surfaces of hessite. R. D. Hall and V. Lenher said that sulphur monochloride converts it into tellurium tetrachloride, etc. G. Tammann studied the chemical activity of the alloys.

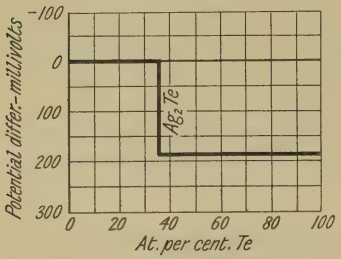

FIG. 14.—Potential Difference of Ag | $\frac{1}{7}N$-AgNO$_3$ | AgTe$_n$.

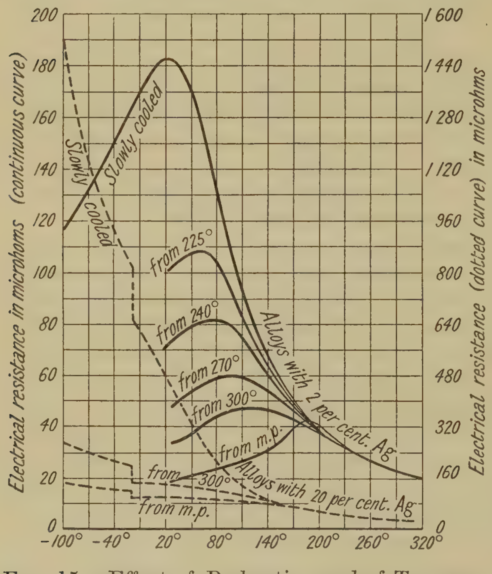

FIG. 15.—Effect of Preheating and of Temperature on the Electrical Resistance of Tellurium-Silver Alloys.

J. A. Krenner,[7] and G. vom Rath described, about the same time, a *krystallisierte Tellurgoldverbindung* from Nagyag, Transylvania. A yellow earth from Nagyag, Transylvania, described by M. H. Klaproth, A. Stütz, W. Phillips, W. Haidinger, and W. H. Miller was probably this mineral. Its occurrences in Cripple Creek, Colorado, was described by A. H. Chester; and in Kalgoorlie, Western Australia, by A. Frenzel, E. F. Pittman, A. Gmehling, M. Maryansky, and K. Schmeisser. J. A. Krenner called it *bunsenine*—after R. Bunsen—and J. D. Dana altered this to *bunsenite;* while G. vom Rath called it **krennerite** because the former term was already in use for native nickelous oxides. The analysis approximates to **silver**

gold ditelluride, $Ag_2Te.Au_2Te_3$, or $AgAuTe_2$, or, as E. S. Simpson writes it, $(Ag, Au_2)Te_4$, Ag.Te.Te.Te.Te.Au. Analyses were reported by M. H. Klaproth, W. Petz, S. Koch, E. H. Liveing, R. Scharizer, L. Sipöcz, A. H. Chester, A. Frenzel, and E. F. Pittman; the analysis by L. Sipöcz was eq. to $Ag_3Au_{10}Te_{26}$. Krennerite occurs in prismatic crystals which are vertically striated. The colour varies from silver-white to brass-yellow. G. vom Rath found that the rhombic crystals have the axial ratios $a:b:c=0·94071:1:0·50445$. Observations on the crystals were made by A. H. Chester, J. A. Krenner, A. Schrauf, L. Sipöcz, and H. A. Miers. The (001)-cleavage is complete. W. M. Davy and C. M. Farnham examined the etched polished surfaces. W. Petz gave 8·27–8·33 for the sp. gr.; A. Frenzel, 8·14; L. Sipöcz, 8·3533. The hardness is 2·5. H. E. McKinstry observed no action when krennerite is exposed to the electric arc-light. R. G. Harvey measured the electrical resistance.

The *Schrifterz*, *Blättererz*, *aurum graphicum*, etc., indicated in connection with the history of tellurium, to which the term **sylvanite**—from Transylvania—was subsequently applied, was analyzed by M. H. Klaproth,[8] J. J. Berzelius, W. Petz, S. Koch, A. Schrauf, L. Sipöcz, F. W. Clarke, P. Krusch, A. Carnot, E. H. Liveing, C. Palache, W. H. Hobbs, F. A. Genth, V. Hanko, and E. S. Simpson. The results agree with the formula $(Au,Ag)Te_2$, in which the at. ratio Au : Ag varies from 1 : 1 to about 6 : 1. The formula $(Au,Ag)Te_2$ was given by G. Rose, and P. Groth. C. F. Rammelsberg, W. Petz, and C. F. Rammelsberg supposed sylvanite to be a mixture of silver monotelluride and gold tritelluride. G. A. Kenngott used the formula $(Au,Ag,Pb)\ (Te,Sb)_2$. The occurrence of the mineral in Nagyag, Offenbanya, Zalathna, and Faczelraja, Transylvania, was described by B. von Cotta, V. von Zepharovich, A. von Groddeck, A. Schrauf, A. Stütz, K. Vrba, and F. Beyschlag; in Hungary, by F. von Richthofen; in California, by J. D. Mathewson, H. J. Burkart, and G. Küstel; in Colorado, by B. Silliman, F. A. Genth, E. P. Jennings, J. D. Dana, C. Palache, W. F. Hillebrand, R. Pearce, and W. H. Hobbs; in South Dakota, by F. C. Smith; in Ontario, Canada, by G. C. Hoffmann; and in Western Australia, by A. Frenzel, and E. S. Simpson.

The mineral occurs in steel-grey to silver-white crystals with more or less of a yellow tinge. J. C. L. Schröder van der Kolk said that the streak of sylvanite is bluish. The crystals were supposed by W. Phillips, and F. Mohs to be rhombic; and J. F. L. Hausmann, and W. H. Miller inclined to the same view. According to N. V. Kokscharoff, the crystals are monoclinic; this view was supported by J. A. Krenner, and A. des Cloizeaux. According to A. Schrauf, the monoclinic crystals have the axial ratios $a:b:c=1·63394:1:1·12653$, and $\beta=89°\ 35'$. Twinning occurs about the (101)-plane, and there is contact twinning, lamellar twinning, and penetration twinning which give rise to branching dendritic forms resembling written characters—hence the terms *Schrifterz*, and *Schrifttellur*. The dendrites usually cross at an angle of 69° 44′—rarely at 55° 8′, or 90°. Skeleton forms are common. The (010)-cleavage is perfect. The crystals were examined by G. Rose, V. von Zepharovich, F. A. Genth, W. H. Hobbs, C. Palache, etc. W. M. Davy and C. M. Farnham examined etched polished surfaces. The sp. gr. given by W. Petz is 8·28; L. Sipöcz, 8·0733; V. Hanko, 8·036; F. A. Genth, 7·943; and C. Palache, 8·161. The hardness is 1·5. J. Joly observed a sublimate of tellurium dioxide is formed below 730° and 780°; and of monoxide between 460° and 520°. E. T. Wherry formed the mineral to be a fair radio-detector. H. E. McKinstry observed no effect by exposing the mineral to the electric arc-light. R. G. Harvey measured the electrical resistance.

W. H. Hobbs described a mineral from Arequa Gulch, Colorado, which he called *goldschmidtite*—after V. Goldschmidt. It occurs in silvery white, monoclinic prisms with the axial angles $a:b:c=1·8561:1:1·2980$, and $\beta=89°\ 11'$. Twinning is common; the (010)-cleavage is perfect; the sp. gr. is 8·6; and the hardness 2. The analysis corresponded with $AgAu_2Te_6$. C. Gastaldi gave $(Au,Ag)_2Te_5$. In view of the variations in the composition of sylvanite, both C. Palache, and E. S. Simpson consider goldschmidtite to be identical with sylvanite.

F. A. Genth found a pale bronze-yellow, massive, indistinctly crystalline mineral in Calaveras Co., California, and in the Red Closed Mine of Colorado ; he called it **calaverite.** Analyses were reported by A. Carnot, F. A. Genth, W. F. Hillebrand, R. W. E. MacIvor, A. G. Holroyd, P. Krusch, E. H. Liveing, W. Lindgren and F. Ransome, S. L. Penfield and W. E. Ford, L. J. Spencer, E. S. Simpson, etc. The composition corresponds with that of krennerite, $(Au,Ag)Te_2$, or in the idealized case, $AuTe_2$. The crystals were stated by S. L. Penfield and W. E. Ford to be monoclinic with the axial ratios $a:b:c=1\cdot6313:1:1\cdot1449$, and $\beta=90°\ 13'$. G. F. H. Smith regarded it as triclinic with the axial ratios $a:b:c=2\cdot0013:1:1\cdot1743$, and $\alpha=83°\ 58'$, $\beta=100°\ 39'$, and $\gamma=90°\ 19'$. M. L. Huggins studied the electronic structure of the crystals. F. A. Genth gave 9·043 for the sp. gr. ; E. S. Simpson, 9·311 ; J. C. H. Mingaye, 9·377 ; and R. W. E. MacIvor, 9·314 ; J. Joly observed a sublimate of tellurium monoxide occurs between 450° and 530°, and of dioxide between 600° and 675°. A. Beutell obtained moss gold by heating the telluride in a sealed tube at 350°–600°. E. T. Wherry found the mineral to be a fair radio-detector. According to L. J. Spencer, when calaverite is heated on charcoal in the oxidizing flame of the blowpipe, the tellurium it contains is readily oxidized, giving rise to the flame, a bead of gold being left behind. When heated in a bulb-tube, calaverite gives a black sublimate of metallic tellurium, and a less volatile sublimate of drops of tellurous oxide (TeO_2), which is yellow when hot and white or colourless when cold ; a yellow malleable bead of gold is not obtained in this way. During the cooling of the beads so obtained, either on charcoal or in the bulb-tube, the interesting phenomenon of recalescence was sometimes observed —after a red-hot bead had become dark it suddenly and momentarily again flashed out red and glowing. This behaviour, which was also exhibited by beads obtained from sylvanite, appeared to depend on the presence of a small amount of tellurium still remaining in the bead. H. E. McKinstry observed no effect when the mineral is exposed to the electric arc-light. R. G. Harvey studied the electrical resistance.

These observations make it appear as if there are three gold tellurides : (1) idealized **gold ditelluride,** $AuTe_2$—namely, rhombic krennerite ; (2) monoclinic sylvanite, and (3) triclinic calaverite. All these minerals contain more or less silver. The thermal diagram for the system : Au–Te was examined by H. Pélabon, and more completely by G. Pellini and E. Quercigh, whose results are summarized in Fig. 16. The alloys were made by direct fusion in an atm. of carbon dioxide. The curve has a single maximum corresponding with gold ditelluride, $AuTe_2$, melting at 464° ; H. Pélabon gave 472° for the m.p. ; and T. K. Rose, 452°. The curve of G. Pellini and E. Quercigh shows two eutectics at 416° with 12 at. per cent. Au, and at 447° with 47 at. per cent. Au. There is no indication of the formation of solid soln. Since the ditelluride cannot be obtained by the action of tellurium on gold salts, it is inferred that the minerals have been formed by fusion processes. M. Coste's observations on the microscopic appearance and the e.m.f. of gold-tellurium alloys showed the gold telluride.

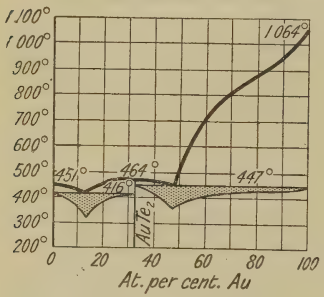

FIG. 16.—Freezing-point Curve of the System : Au–Te.

E. H. Liveing described a white mineral with a bismuth tinge of colour from Kalgoorlie, West Australia. He called it *speculite.* It has the perfect cleavage of sylvanite and a sp. gr. of 8·64. The analysis indicates 36·1 to 36·6 per cent. of gold, 3·50 to 4·45 per cent. of silver, and the rest tellurium.

J. J. Berzelius reported **gold hemitelluride,** Au_2Te, to be formed by heating gold sulphotelluride, $Au_2S_3.TeS_2$, so as to drive off the sulphur ; B. Brauner[9] said that when the alloys of tellurium are heated to redness in a current of carbon dioxide, they dissociate into a mixture of the hemitelluride and gold. J. Margottet said that the hemitelluride is formed when the vapour of tellurium is passed over leaf gold heated in the absence of air. V. Lenher was unable to prepare a gold telluride by heating a mixture of the two elements; and when hydrogen telluride is passed into a soln. of auric chloride, gold is precipitated. If a soln. of auric chloride be treated with tellurium, gold is deposited and tellurium tetrachloride is formed: $4AuCl_3+3Te=4Au+3TeCl_4$. He also found that the natural tellurides—calaverite, sylvanite, coloradoite, kalgoorlite, and nagyagite—the gold-tellurium alloys behave in a similar manner. Hence, it was inferred that these tellurides are not to be regarded as chemical individuals. L. Nowack observed that the alloys with gold and tellurium are very brittle. C. A. Tibbals found that sodium telluride precipitates gold and tellurium from soln. of sodium tellurate, but the substances formed do not appear to be of constant composition. When sodium telluride reacts with an excess of neutral auric chloride soln., a precipitate of metallic gold is formed which contains no tellurium. This may be due to one of two reactions, *viz.* a telluride of gold may be formed which at once reacts with the excess of nitric chloride, reducing it in a manner similar to the action of the natural tellurides; or the sodium telluride may act simply as a reducing agent toward the auric chloride according to the equation: $2AuCl_3+Na_2Te=2NaCl+TeCl_4+2Au$. A. Brukl obtained **auric telluride,** Au_2Te_3, by the action of hydrogen telluride on an ethereal soln. of auric chloride since in aq. soln. the compound is decomposed. The black, flocculent telluride is soluble in soln. of ammonium hydrotelluride and sodium telluride, and only slightly soluble in soln. of ammonium sulphide or sodium sulphide. Non-oxidizing acids are without action, but nitric acid dissolves the tellurium and leaves the gold behind.

The mineral hessite, in the idealized case, is silver hemitelluride, Ag_2Te, but it is nearly always auriferous, and to distinguish the two, J. F. L. Hausmann called the former *Tellursilber* and the latter, *Tellurgoldsilber;* and W. Haidinger proposed to call the auriferous varieties **petzite**—after W. Petz. The analyses and occurrences are included in the description of hessite. Like hessite it crystallizes in the cubic system. The idealized mineral can be regarded as gold hemitelluride, Au_2Te, actually it is a silver gold hemitelluride, $(Au,Ag)_2Te$. J. Joly found that a sublimate of tellurium dioxide is formed at 750°. E. T. Wherry found the mineral to be a poor radio-detector. According to L. J. Spencer, when heated on charcoal in the oxidizing flame of the blowpipe, petzite produces only slightly the bluish-green coloration of the flame and the dense white fumes characteristic of tellurium; only when fused with sodium carbonate does it give a white malleable bead, and this when placed in nitric acid becomes yellow. Calaverite and sylvanite, on the other hand, are much less stable, and are readily converted into a bead of gold by simply heating on charcoal in the oxidizing flame; this, however, takes place much more readily with calaverite than with sylvanite, since the latter contains more silver in combination with the tellurium. H. E. McKinstry observed no effect by exposing the mineral to the electric arc-light. According to F. Zambonini, the analyses of krennerite fall into two groups: those containing but little silver and with the ditelluride formula $(Au,Ag)Te_2$; and those containing about 20 per cent. silver, which have the monotelluride formula $(Ag,Au)Te$. Crystals of the former group are identical with the orthorhombic krennerite; and those of the latter group are taken to represent a distinct species for which the name **muthmannite**—after W. Muthmann—was proposed. Analyses by A. Schrauf, S. Koch, R. Scharizer, and C. Gastaldi agree with the formula for **silver gold monotelluride,** $(Au,Ag)Te$, or in the idealized case, **gold monotelluride,** $AuTe$. Externally, muthmannite resembles krennerite, but the imperfect crystals are tabular and often elongated in one direction, parallel to which direction there is a perfect cleavage. The colour is very pale brass-yellow, but on a fresh cleavage, greyish-white. A. D. Alvir described a gold silver telluride from Antamok, Philippine Islands, which he called *antamokite*.

M. Berthelot and C. Fabre[10] obtained **calcium telluride,** presumably $CaTe$, by heating calcium tellurite with carbon in a current of hydrogen. It is decomposed by acids with the evolution of hydrogen telluride, rapidly if the telluride is powdered, and slowly if it be in lumps. M. Berthelot and C. Fabre obtained **strontium telluride** in a similar way; and also **barium telluride.** F. A. Henglein and R. Roth could not make the alkaline earth tellurides by the methods they used for the selenides. M. Haase gave 4·87 for the sp. gr. and 54·41 for the mol. vol. of calcium telluride; respectively 5·22 and 41·21 for strontium telluride; and respectively 5·51 and 48·08 for barium telluride. The X-radiograms show that the space-lattices of calcium and strontium tellurides have the sodium chloride structure with a respectively 3·20 A., and 3·34 A. V. M. Goldschmidt gave $a=6·343$ A. for calcium telluride, and I. Oftedal, $a=6·345$ A., while M. Haase gave $a=6·82$ to 6·86 A. for barium telluride, 6·48 A. for strontium telluride, and 6·1 A. for calcium telluride. He also gave for the ionic distances 3·05 A. for calcium telluride, 3·26 A. for strontium telluride, and 3·41 A. for barium telluride. L. Pauling discussed the structure. K. Spangenberg found the crystal structure of barium telluride to be of the sodium chloride type with a density of 7·593. He also found the index of refraction and the mol. refraction to be respectively 2·51, and 22·04 for calcium telluride; 2·408, and 25·39 for strontium telluride; and 2·440, and 29·94 for barium telluride. I. Oftedal discussed the lattice constants of calcium telluride. M. Haase found the index of refraction for the D-line to be between 2·51 and 2·58 for calcium telluride; and for the Tl-, D-, and C-lines respectively 2·460, 2·448, and 2·367 for strontium telluride, and 2·520, 2·440, and 2·379 for barium telluride. For the mol. refraction of calcium, strontium, and barium tellurides, he gave respectively 21·99, 24·38, and 29·95. F. Wöhler prepared **beryllium telluride,** as a grey powder, by heating a mixture of the two elements. Combination occurs without incandescence; and the cold product gives off hydrogen telluride when treated with water. W. Zachariasen gave $a=5·615$ A. for the side of the face-centred lattice of beryllium telluride. M. Berthelot and C. Fabre obtained **magnesium telluride,** presumably MgTe, by heating magnesium in the vapour of tellurium carried by a current of hydrogen. If a mixture of tellurium and magnesium be heated to dull redness, a reaction sets in with explosive violence. W. Zachariasen found that while magnesium oxide, sulphide and selenide have the sodium chloride structure, magnesium telluride has the wurtzite space-lattice with side $a=4·52$ A., $c=7·33$ A., and $a:c=1:1·622$; the calculated density is 3·86, and the shortest distance between the magnesium and tellurium atoms is 2·76 A. M. Haase gave 26·83 for the mol. vol. K. Spangenberg found the index of refraction to be 3·05, and the mol. refraction 29·94; while M. Haase gave 3·50 for the index of refraction for the D-line. White, flocculent magnesium telluride quickly turns brown when exposed to air, it dissolves in water forming a purple-red soln. if the water is only slightly aërated, but if the water is charged only with nitrogen, the aq. soln. is colourless. Acidulated water acts on the telluride with the evolution of hydrogen telluride. L. Moser and K. Erth prepared magnesium telluride, as a brown sintered mass, by distilling tellurium at a low press. over finely-divided magnesium. D. M. Liddell made it by dropping tellurium into molten magnesium. According to A. Hilger, and K. B. Heberlein, an ammoniacal soln. of a magnesium salt in the presence of an aq. soln. of an alkali telluride gives a precipitate of **ammonium magnesium telluride.**

J. J. Berzelius[11] found that when a mixture of zinc and tellurium is heated union occurs with incandescence, and a grey porous, crystalline mass is produced which is not soluble in dil. sulphuric acid or conc. hydrochloric acid. J. Margottet obtained **zinc telluride,** ZnTe, by heating a mixture of the component elements; and C. A. Tibbals obtained it in a similar way. M. Kobayashi found that alloys of tellurium and zinc furnish a f.p. curve, Fig. 17, which shows the existence of only one compound, ZnTe, with a maximum at 1238·5°. The two eutectic points practically coincide with the m.p. of the pure components. The f.p. curve falls steadily from the compound to tellurium, but alloys richer in zinc lose zinc so rapidly by volatilization that it is not possible to determine the course of the curve, although the zinc eutectic arrest is well marked. H. St. C. Deville and L. Troost obtained cubic crystals of the telluride by passing hydrogen over zinc telluride heated to bright redness. L. Moser and K. Erth prepared zinc telluride, as a pale brown mass, stable in air, by distilling tellurium at a low press. over finely-divided zinc. E. Kordes studied the eutectic. M. Kobayashi obtained the telluride as a mass of microscopic needles of sp. gr. 5·54 at 13°. W. Zachariasen found that the X-radiograms indicate that the cubic space-lattice, of the zinc blende type, has four mols. per cell; the edge-length of the cells is 6·07 A.; and the calculated density is 5·72. By a double decomposition of soln. of sodium telluride and zinc acetate in acetic acid soln., C. A. Tibbals obtained a yellowish-brown precipitate of the *monohydrate*, $ZnTe.H_2O$; this turns brown when dried. The compound was also prepared by A. Brukl. F. Henglein gave 29·5 for the mol. vol. M. L. Huggins studied the atomic structure of the crystals. W. Zachariasen gave $a=6{\cdot}089$ A. for the side of the face-centred lattice. It is decomposed by dil. hydrochloric acid; it is oxidized by nitric acid; and unaffected by dil. sulphuric acid; it gives the dark red anhydride when heated out of contact with air. C. Fabre gave 37·22 Cals. for the heat of formation of the crystalline telluride.

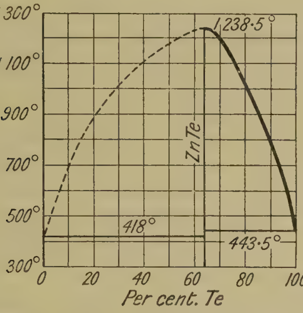

FIG. 17.—Freezing-point Curve of the System: Zn–Te.

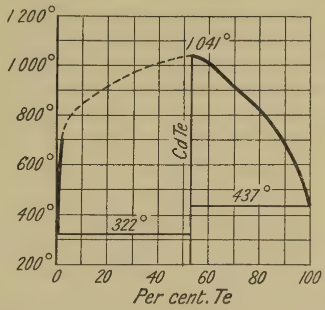

FIG. 18.—Freezing-point Curve of the System: Cd–Te.

A. Oppenheim obtained impure **cadmium telluride,** CdTe, by heating cadmium tellurite or tellurate to redness in a current of hydrogen. The black powder yields a porous, grey mass when heated more strongly. J. Margottet prepared this compound by melting together eq. proportions of the two elements at 500°, and subliming the product slowly in a current of hydrogen. M. Kobayashi made alloys by fusing mixtures of the two elements in glass or porcelain tubes in an atm. of carbon dioxide. The f.p. curve, Fig. 18, has a maximum at about 1041°, corresponding with the compound TeCd, but it is not possible to prepare this compound in a pure condition under ordinary press., owing to the volatility of cadmium. The two eutectic points lie so near to the f.p. of cadmium and tellurium respectively as to be indistinguishable from them. W. Zachariasen found that the X-radiogram agrees with a cubic space-lattice, containing four mols. per cell which is of the zinc blende type with the edge-length of the cell 6·41 A.; and the density, 6·06. W. Hartvig also said that the space-lattice is of the zinc blende type. C. A. Tibbals, and A. Brukl obtained the telluride by treating a soln. of cadmium in acetic acid with sodium telluride. M. L. Huggins studied the atomic structure of the crystals. C. Fabre gave for the heat of formation: (Cd,Te)=20 Cals. C. A. Tibbals said that the chestnut-brown precipitate dries almost black; it is easily oxidized by moist air; and is very resistant towards acids; nitric acid alone attacks it in the cold. A. Brukl observed no sign of the complex $2CdTe.CdCl_2$.

F. A. Genth[12] described an iron-black mineral which occurs at Keystone, Colorado, and which he called **coloradoite.** The analysis was made on impure samples, but the results were taken by F. A. Genth, and C. F. Rammelsberg to indicate that idealized coloradoite is **mercury monotelluride,** HgTe, mixed with native tellurium. E. S. Simpson analyzed a sample from West Australia and gave the representative formula Hg_2Te_3; but L. J. Spencer found that selected samples of homogeneous material from the same locality gave results in agreement with the monotelluride formula. L. Rivot, and G. A. Kenngott described impure mercury telluride from Chili: and W. F. Hillebrand, from California. The mineral occurs massive and granular. L. J. Spencer thus described the mineral from West Australia. It is iron-black, opaque, with a bright metallic lustre, an excellent conchoidal fracture, but no indication of cleavage. W. Zachariasen found that the X-radiogram of the monotelluride agrees with a cubic space-lattice, of the zinc blende type, with four mols. per cell; the edge-length of the cell is a=6·36 A.; and the calculated density is 8·42. F. de Jong found a=6·43 A.; density 8·20; and the distance between the mercury and tellurium atoms 2·78 A. M. L. Huggins studied the atomic structure of the crystals. The mineral is brittle and extremely friable. W. M. Davy and C. M. Farnham studied the etching of polished surfaces of the mineral. For impure samples, F. A. Genth gave 8·627; and E. S. Simpson, 9·21; but for more pure samples, L. J. Spencer gave 8·062 to 8·077—mean, 8·07. According to L. J. Spencer, tetrahedral cubic crystals of metacinnabarite, HgS, have a sp. gr. 7·81; those of tiemannite, 8·19; but coloradoite, instead of having a greater sp. gr. has a smaller one. F. Henglein gave 38·0 for the mol. vol. J. Joly observed a sublimate of tellurium monoxide occurs at 20°, and of the dioxide at 835°. F. A. Genth gave for the hardness, 3·0; L. J. Spencer, 2·5. F. Beijerinck, and R. D. Harvey said that it is a good conductor of electricity; and E. T. Wherry found it to be a fair radio-detector. P. I. Wolf and J. M. Hyatt studied the Hall effect with tellurium amalgams. L. J. Spencer said that when coloradoite is heated on charcoal, it readily fuses and colours the flame bright bluish-green, emits dense white fumes, and in a very short time completely disappears. In the closed tube it fuses with spluttering to a black globule, and gives a sublimate of globules of mercury and a much less volatile sublimate of drops of tellurous oxide, the latter being yellow when hot and white or colourless when cold; with a larger fragment of material a black sublimate of metallic tellurium is also obtained.

Both M. H. Klaproth, and J. J. Berzelius noted the ease with which tellurium amalgamates with mercury, and they prepared tin-white, and granular *tellurium amalgams;* and G. Pellini and C. Aureggi found that mixtures of mercury and powdered tellurium react readily on heating with development of a considerable amount of heat. When 66 at. per cent. or more of tellurium are present, the mixture fuses completely, whilst mixtures less rich in tellurium decompose at a high temp. with liberation of mercury. The solidification curves of mixtures containing from 60 to 65 at. per cent. of tellurium exhibit a eutectic temp. halt at about 410°, Fig. 19. The form of the curves indicates the existence of a mercuric monotelluride, which, however, melts with decomposition at the ordinary press., its upper limit of stability being about 550°. The eutectic Te+HgTe corresponds with 87 at. per cent. of tellurium, and has a distinctly crystalline appearance. Tellurium dissolves only slightly in mercury. When triturated in a mortar at the ordinary temp., mercury and tellurium yield a greyish-white paste with a metallic lustre, from which, after a long time, or by gently heating, the monotelluride may be isolated. A. C. Vournasos obtained the monotelluride by heating the constituents under melted paraffin. J. Margottet found that the

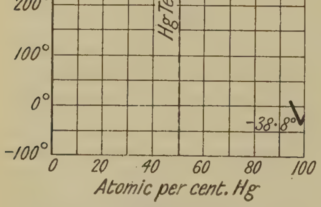

FIG. 19.—Freezing-point Curve of the System: Hg–Te.

vapours of the two elements at about 800° unite with a small explosion, with the evolution of heat. The black powder which is formed suffers a little dissociation at 360°. F. Krafft and R. E. Lyons obtained the telluride by the action of tellurium dichloride on mercury phenide. C. A. Tibbals observed that sodium telluride soln. precipitates from mercuric chloride soln., a grey substance, which changes first to a yellow and then to a red colour, and finally to a homogeneous light brown. The final product is mercurous chloride, and tellurium is found to be dissolved in the soln. Mercuric telluride is probably formed at first, but subsequently reacts with the excess of mercuric chloride reducing it to mercurous chloride with the formation of tellurium chloride. A. Brukl obtained it by the action of hydrogen telluride on soln. of mercuric salts. Mercury monotelluride is not stable in air, but readily decomposes into its components. It is a little soluble in a mixed soln. of sodium sulphide and hydroxide, but not in ammonium sulphide; it is a little soluble in a soln. of ammonium hydrotelluride. Mercuric chloride soln. are reduced. Mercuric telluride is easily oxidized by nitric acid, and acids decompose it into its elements without forming hydrogen telluride. A. Brukl could not prepare *mercurous telluride*, Hg_2Te, by the action of hydrogen telluride on a soln. of a mercurous salt The product is a mixture of tellurium and mercury.

E. F. Pittman described an iron-black mineral from Kalgoorlie, West Australia, and he called it *kalgoorlite*. The analysis corresponded with $HgAu_2Ag_6Te_6$; and the sp. gr. was 8·791. E. S. Simpson, and L. J. Spencer also analyzed a sample with results in agreement with this. A. Carnot previously applied the term kalgoorlite to a mercurial petzite from the same locality. T. A. Richard, and E. H. Liveing regarded it as a mixture of petzite and coloradoite; and this was proved to be the case by L. J. Spencer—thus, $HgAu_2Ag_6Te_6 = HgTe(\text{coloradoite}) + 2Ag_3AuTe_2(\text{petzite}) + Te$. H. E. McKinstry observed no effect when the mineral is exposed to the electric arc-light. A. Carnot also described a mineral from the East Coolgardie gold field, West Australia, as a sesquitelluride of gold, silver, and mercury, $(Au, Ag, Hg, Cu, Fe, Sb)_2Te_3$, or $(Au, Ag, Hg)_2Te_3$. It was called **coolgardite.** The analyses differ widely, and L. J. Spencer showed that coolgardite is probably not a distinct, homogeneous individual, but rather a mixture of coloradoite, calaverite, petzite, and sylvanite.

H. Moissan[13] observed that boron does not combine with tellurium to form a *boron telluride*. F. Wöhler prepared presumably normal **aluminium telluride,** Al_2Te_3, by heating a mixture of the powdered elements; a vigorous reaction sets in, with incandescence. M. Chikashige and J. Nosé made a similar observation. C. Whitehead said that this telluride is formed when variable quantities of the two elements are melted together. D. M. Liddell made the telluride by dropping tellurium into molten aluminium. R. de Forcrand and H. Fonzes-Diacon inflamed a mixture of the powdered elements by means of a piece of magnesium ribbon. M. Chikashige and J. Nosé studied the f.p. curve of the mixtures, and their results are summarized in Fig. 20. The f.p. curve on the tellurium side shows the formation of the normal telluride Al_2Te_3, of m.p. 895°. This telluride forms mixed crystals with tellurium, the series extending from the pure compound (12·4 per cent. by weight of aluminium) to a mixture which contains 4·4 per cent. of aluminium. On cooling, the α-mixed crystals undergo transformation into β-mixed crystals. The temp. at which this conversion takes place diminishes with increase in the tellurium content, and for the sat. α-mixed crystals falls to 541°. The β-mixed crystals and tellurium co-exist at the eutectic temp. 414°, the eutectic mixture containing 2·8 per cent. of aluminium. L. Moser and K. Erth prepared aluminium telluride as a blackish-brown, amorphous mass, by passing the vapour of tellurium, under

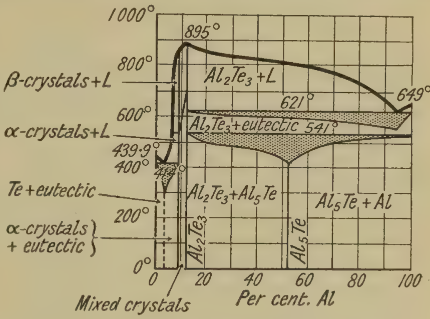

Fig. 20.—Freezing-point Curves of Mixtures of Aluminium and Tellurium.

reduced press., over finely-divided aluminium. A. L. Pocock and co-workers discussed the preparation of Al-Te-alloys. The telluride may appear as a black, brittle mass with a metallic appearance, or it may be a chocolate-brown powder. It smells of hydrogen telluride, and gives off that gas vigorously when treated with water or in contact with moist air: $Al_2Te_3+3H_2O=3H_2Te+Al_2O_3$. L. Moser and K. Erth also said that aluminium telluride decomposes in air forming hydrogen telluride; and they recommended the dropping of aluminium telluride into dil. acid as a mode of preparing hydrogen telluride. G. Natta studied the action of the telluride on alcohols and ethers. The f.p. curve of mixtures of aluminium and tellurium on the aluminium side of the Al_2Te_3-curve is terminated by a eutectic point, in which the telluride and aluminium co-exist in equilibrium. The eutectic mixture contains 97 per cent. of aluminium and the eutectic temp. is 621°. The conglomerates, consisting of the telluride or aluminium and the eutectic, undergo transformation when the temp. has fallen to 551° with the formation of **aluminium pentitatelluride,** Al_5Te, according to the equation: $Al_2Te_3+13Al=3Al_5Te$. The compound Al_5Te is less readily decomposed, but hydrogen telluride is liberated in contact with water, the reaction being possibly represented by $Al_5Te+H_2O+O_2=TeH_2+Al_2O_3+3Al$. F. T. Sisco and M. R. Whitmore studied some ternary alloys of aluminium, copper, and tellurium.

According to C. Renz,[14] indium and tellurium unite with incandescence when the mixture is heated forming, presumably, **indium telluride,** In_2Te_3. According to H. Pélabon, tellurium unites with thallium when the two elements are melted together, forming **thallium hemitelluride,** Tl_2Te, when more than 24 per cent. of Tl is present. A. Brukl prepared this telluride by the action of hydrogen telluride on an ammoniacal soln. of a thallous salt. It is easily decomposed, and gives hydrogen telluride with acids. C. Fabre gave 12·24 for the heat of formation of crystallized thallous telluride. G. Tammann studied the chemical activity of the alloys. This compound melts at 412°, and as the proportion of thallium diminishes, the m.p. curve rises to a maximum at 422°, corresponding with the compound **thallium pentitatritelluride,** Tl_5Te_3, or $Tl_2Te_3.9Tl_2Te$. The curve then falls to a minimum at 214° representing, presumably, the eutectic mixture $2Tl+5Te$; and it finally rises to 452°, the m.p. of tellurium alone. M. Chikashige's f.p. curve, Fig. 21, shows only a single maximum at 428° corresponding with **thallium tritaditelluride,** Tl_3Te_2, and the break in the curve at 305° and 40·5 per cent. of tellurium corresponds with **thallium monotelluride,** TlTe. The eutectic point lies at 200° and 58·5 per cent. Te. The alloys separate into two liquid layers between the limits 1·5 and 24 per cent. Te at 393°. Solid soln. are formed only by the compound Te_2Tl_3 with 5·5 per cent. of thallium. This compound is very brittle, whilst the compound TeTl, which forms long needles, is much less so.

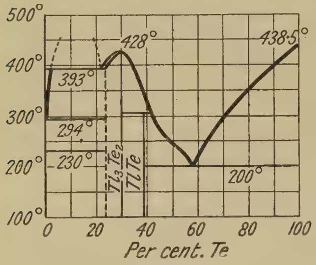

FIG. 21.—Freezing-point Curve of the System: Tl–Te.

According to A. Stock and H. Blumenthal,[15] when an arc is formed under carbon disulphide between a tellurium cathode and a graphite anode the tellurium is rapidly vaporized, and condenses, for the most part, in the form of a fine black powder. At the same time the carbon disulphide becomes yellow to brownish-red in colour, and acquires a penetrating, very disagreeable odour. On exposure to daylight, the filtered soln. soon, and in direct sunlight immediately, deposits a black precipitate. If the yellow soln. is concentrated by evaporation on the water-bath, and then heated in a sealed evacuated tube at 175° for forty-eight hours, a greyish-black deposit is obtained, the carbon disulphide not being affected. Analyses agreed with the assumption that the unstable compound dissolved in carbon disulphide, and which is readily decomposed by exposure to light or heat, is **carbon ditelluride,** CTe_2. On evaporating the yellow soln. in carbon disulphide, it leaves a viscid, brown residue, which will again dissolve to a yellow soln. if immediately treated with the solvent, but otherwise becomes solid and greyish-black in a few seconds, decomposing into carbon and tellurium. The same soln. at —100° gives glistening, brown crystals, which dissolve on slightly raising the temp. The soln. of carbon telluride has an unbearable penetrating odour, even when so dilute as 0·1 per cent. Smelling a somewhat stronger soln. for only a short time is enough to impart an intense odour of garlic to the breath for several days. A. Stock and P. Praetorius showed that the phenomena are due to the decomposition of carbon sulphotelluride—*vide infra.* There is no evidence that carbon ditelluride has been prepared. I. Oftedal prepared small, tabular, red crystals of **titanium telluride,** $TiTe_2$, by heating a mixture of powdered titanium and tellurium. The X-radiograms show that the crystals have a structure like cadmium iodide-stannic sulphide, and titanium sulphide and selenide. The hexagonal lattice has $a=3·774$ A., and $c=6·539$ A., or $a:c=1:1·732$. The calculated sp. gr. is 6·24. G. Natta, and V. M. Goldschmidt studied this subject. J. J. Berzelius observed that tellurium readily alloys with tin, and A. Ditte found that **tin monotelluride,** or **stannous telluride,** SnTe, is produced when the two elements in theoretical proportions are melted together. Combination occurs with incandescence as soon as the tin melts. If the matte-grey powder be heated to bright redness in a current of hydrogen, it forms a green vapour, and slowly distils. D. M. Liddell made the alloy by dropping tellurium into molten tin. H. Pélabon found that the f.p. curve of tin rises with the addition of tellurium rapidly and then more gradually until a maximum at 780° is attained corresponding with the monotelluride; the curve then falls rapidly to a minimum curve at 388°, the f.p. of the eutectic with 17 per cent. of tellurium. It then rises to 452°, the m.p. of tellurium. There is no sign of either Sn_2Te_3 or of $SnTe_2$ on the f.p. curve. In H. Fay's curve, the maximum for SnTe is at 769°, and the eutectic at 399° and 85 per cent. Te; the other eutectic has a very low proportion of tellurium. In W. Biltz and W. Mecklenberg's curve, Fig. 22, the maximum for SnTe is at 800°, and a eutectic at 404° and 85 per cent. Te. M. Kobayashi obtained a maximum at 780°, and a eutectic at 393° with 86 per cent. of tellurium. E. Kordes studied the eutectics. A. Brukl obtained stannous telluride, SnTe, by the action of hydrogen telluride on a soln. of stannous chloride. W. Harz gave $3·07\times10^{12}$ for the vibration-frequency. W. Haken's observations on the electrical conductivities of the alloys are summarized in Fig. 23; and his observations on the thermoelectric powers are summarized in Fig. 24. Well-dipped breaks occur corresponding with the monotelluride. Between 55 and 100 per cent. of Sn, the

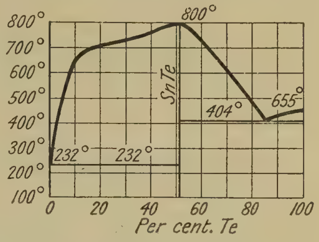

FIG. 22.—Freezing-point Curve of Tin and Tellurium.

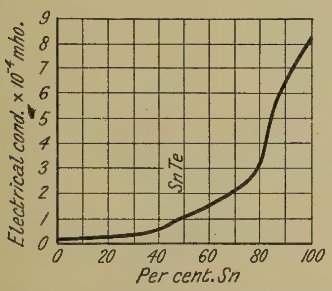

FIG. 23.—The Electrical Conductivities of the Sn–Te Alloy.

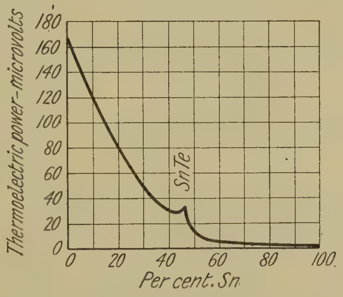

FIG. 24.—The Thermoelectric Powers of the Sn–Te Alloys.

thermoelectric power curve is a straight line of small slope. N. A. Puschin observed that the grey alloys of tellurium and tin are brittle, and that the electrode potential difference with the cell Sn | N-H_2SO_4 | $SnTe_n$ has a break corresponding with the monotelluride, as shown in Fig. 25. The observations of K. Honda and T. Sone on the magnetic susceptibilities of the solid and liquid alloys, are summarized in Fig. 26. The curve consists of two straight lines which intersect at the concentration corresponding with the monotelluride. H. Endo also studied the magnetic properties of the alloy. A. Ditte said that when the monotelluride is heated with a conc. soln. of alkali sulphide, tellurium sulphostannate is not formed, but tellurium separates in fern-like, rhombohedral plates. A. Brukl made **stannic telluride** or **tin ditelluride,** $SnTe_2$, by the action of hydrogen telluride on a soln. of a stannic salt. The black flocculent precipitate is insoluble in water, but it readily dissolves in soln. of ammonium sulphide, or of alkali hydroxide. The latter soln. is red, but it becomes colourless in air with the separation of a grey powder. It is decomposed by dil. acids. G. Tammann studied the chemical activity of the Se-Te alloys.

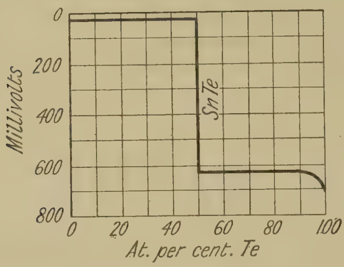

FIG. 25.—Electromotive Force of the Cell Sn | N-H_2SO_4 | $SnTe_n$.

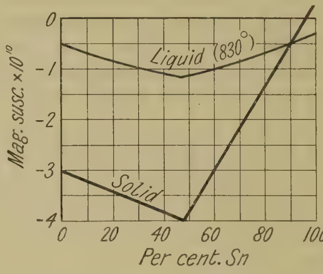

FIG. 26.—Magnetic Susceptibility of the Sn–Te Alloys.

G. Rose[16] obtained a mineral from Altai, Urals, which he described as a telluride of lead; and it was called **altaite** by W. Haidinger. F. S. Beudant employed J. J. N. Huot's term for nagyagite, namely, *elasmose.* H. Louis described its occurrence at Choukpazat, Upper Burma; I. Domeyko, in Condorriaco, Chili; C. A. Stetefeldt, and F. A. Genth, in Calaveras Co., California; W. T. Schaller, Tuolumne Co., California; F. M. Endlich, and F. A. Genth, at Goldhill, Colorado; F. A. Genth, in Gaston Co., North Carolina; G. C. Hoffmann, in Kootanie, and Yale, British Columbia; A. des Cloizeaux, Bontddu, North Wales; and L. J. Spencer, and E. S. Simpson, Kalgoorlie, West Australia. Analyses of altaite were reported by G. Rose, H. Louis, F. A. Genth, G. C. Hoffmann, W. T. Schaller, and E. S. Simpson. The results agree that altaite is a **lead monotelluride,** PbTe, in which a little silver may replace lead, and a little sulphur or selenium may replace tellurium. The mineral usually occurs massive, rarely in cubes.

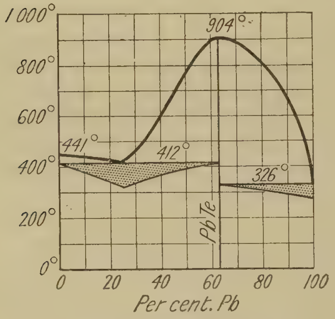

FIG. 27.—Freezing-point Curve of Lead and Tellurium.

J. J. Berzelius observed that lead and tellurium readily form alloys when a mixture of the two elements is melted. H. Fay and C. B. Gillson added tellurium to lead melted under a layer of charcoal; and W. Haken melted the mixture in hydrogen gas. D. M. Liddell made the alloy by dropping tellurium into molten lead. Alloys were also made by M. Dreifuss, N. A. Puschin, C. A. Tibbals, H. Pélabon, A. C. Vournasos, and M. Kimura. J. Margottet said that union occurs at about 500°, and is attended by the evolution of heat and light. C. Fabre made the monotelluride by passing the vapour of tellurium, in a current of nitrogen, over heated lead. C. A. Tibbals obtained PbTe by heating Pb_2Te_3 to redness; and A. Brukl, by adding sodium telluride to a soln. of a lead salt. According to H. Pélabon, the f.p. curve has a maximum at 860° corresponding with the monotelluride and a eutectic at 452° with 9·5 at. per cent. of tellurium. H. Fay and C. B. Gillson added that the lead easily becomes supersaturated with respect to lead telluride, which separates out at the higher f.p., and the lower f.p. then corresponds with the solidification of the lead. When still more tellurium is present, lead telluride again separates at the higher temp., but the lower f.p. corresponds with the complete solidification of the alloy, which is an eutectic of lead telluride and tellurium. According to M. Kimura, the f.p. curve is of the simple type, Fig. 24, with only one compound, PbTe, melting at 904°; there is a eutectic at 412° with 24 per cent. of lead; the other eutectic is practically coincident with pure lead. A. Mazzucchelli and A. Vercillo did not obtain a definite lead telluride by the action of lead on tellurium tetrachloride. E. Kordes studied the eutectics.

The colour of altaite is tin-white, with a yellowish tinge tarnishing to bronze-yellow. The cleavage is cubic. According to N. A. Puschin, the tellurium-lead alloys are grey and crystalline, with a fine-grained fracture. H. Fay and C. B. Gillson said that the microstructure shows a eutectic interspersed with crystals of lead or tellurium according to which is present in excess; and M. Kimura found the microstructure to be in accord with the thermal diagram. C. H. Green studied the Pb–Te eutectics. W. M. Davy and C. M. Farnham examined polished and etched surfaces of altaite. L. S. Ramsdell found that the X-radiogram showed that the face-centred space-lattice is like that of galena; with a=6·34 A. L. Pauling discussed the lattice-structure. G. Rose gave 8·16 for the sp. gr. of altaite; F. A. Genth, 8·060; G. C. Hoffmann, 8·081; and E. S. Simpson, 8·223. F. Henglein gave 40·7 for the mol. vol. H. Fay and C. B. Gillson found that alloys with over 50 per cent. of tellurium are very brittle; and that their hardness increases as the proportion of tellurium increases. According to P. Saldau, the curve of hardness for the system Pb-Te shows for the compound PbTe (altaite) a hardness of 31·85 kg. per sq. mm. considerably in excess of that of either of the components (Pb 3·92, Te 18·43 kg. per sq. mm.). The maximum degree of hardness (33·58 kg. per sq. mm.) corresponds with a content of Te 49·8 at. per cent. In the system PbTe–Pb, lead telluride enters into solid soln. only to a limited extent, whilst in the system PbTe–Te it fails to do so. The m.p. given by H. Pélabon is 860°; and by M. Kimura, 904°. J. Margottet observed that volatilization occurs at a bright red-heat, and cubic crystals deposit in the cold part of the tube. J. Joly observed that a sublimate of tellurium dioxide occurs with altaite at 710° to 850°. C. Fabre gave 11·429 Cals. for the heat formation. E. T. Wherry found altaite to be a poor radio-detector; R. G. Harvey studied the electrical resistance; and T. W. Case observed that light has no measurable effect on the electrical resistance of altaite. W. Haken found that the thermal e.m.f. of the lead-tellurium alloys is a minimum, —70 microvolts, with the monotelluride. N. A. Puschin measured the potential difference with the cell Pb | N-$Pb(NO_3)_2$ | $PbTe_n$, and found a marked break corresponding with the monotelluride; thus,

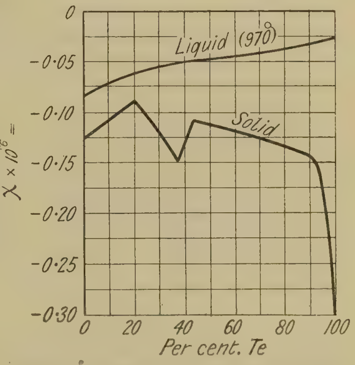

FIG. 28.—Magnetic Susceptibility of the Pb–Te Alloys.

At. per cent. Te .	15	33	46	50	66	100

H. Endo, and K. Honda and T. Sone measured the magnetic susceptibility of the solid and liquid alloys, and their results are summarized in Fig. 28. H. Endo also studied the magnetic properties of the alloys. H. Fay and C. B. Gillson found that chlorine passed over the heated alloy forms tellurium tetrachloride which can be distilled off; and C. Fabre said that the heat of soln. in bromine or bromine water is 104·76 Cals. K. B. Rogers found that altaite is decomposed when it is heated in the vapour of carbon tetrachloride.

C. A. Tibbals found that when a soln. of sodium polytelluride is added to a soln. of lead acetate in acetic acid, a heavy black precipitate of hydrated **lead hemitritelluride,** $Pb_2Te_3.4H_2O$, is formed. The *tetrahydrate* is oxidized by nitric acid; but is not attacked by sulphuric and hydrochloric acids; it loses water when heated in a current of hydrogen, fuses, and as the heat is increased, tellurium volatilizes leaving the monotelluride as a residue. G. Tammann studied the chemical activity of the lead-tellurium alloys.

According to R. Metzner,[17] dried liquid ammonia, at —15°, acts on tellurium tetrachloride, so as to form a yellow substance accompanied by an expansion. This product is a mixture of white ammonium chloride and a yellow substance. The solid is washed by decantation, and then with water to get rid of the last traces of ammonium chloride; it is then washed with dil. acetic acid, and finally with water. When dried in vacuo and analyzed, the composition of the lemon-yellow, amorphous mass agrees with **nitrogen monotelluride,** NTe. It explodes when heated to 200°, producing tellurium as a black dust. It is not attacked by water or dil. acetic acid; it is insoluble in liquid ammonia; and with potash-lye, all the nitrogen is evolved as ammonia. The compound was also obtained by M. Damiens. W. Strecker and W. Ebert said that if ammonia acts on tellurium tetrachloride or tetrabromide at —80°, the primary action results in the formation of a hexammine, and this is followed by the gradual replacement of the halogen atoms by the amido-group; then by loss of ammonia into imide and ultimately nitride. The ammonolysis proceeds in accord with $3TeBr_4+4NH_3=Te_3Br_9N+3NH_4Br$; $3TeBr_4+8NH_3=Te_3Br_6N_2+6NH_4Br$; and $TeBr_4+4NH_3=TeBrN+3NH_4Br$. It is supposed that the TeN-compound is really an impure tellurium bromonitride, and that the product is **tellurium tritatetranitride,** Te_3N_4. The ultimate reaction is probably in accord with $3TeBr_4+16NH_3=Te_3N_4+12NH_4Br$. A. Oppenheim[18] observed that a *tellurium phosphide,* or phosphorus telluride, is produced by warming powdered tellurium and phosphorus in a glass tube; but the product has not been investigated.

A. Oppenheim[19] prepared **arsenic telluride,** As_2Te_3, as well as AsTe, in the form of white, brittle alloys, by melting together the constituent elements in these proportions; and similarly E. C. Szarvasy and C. Messinger, an alloy of the composition As_8Te_3. It dissociates when vaporized. It is insoluble in ordinary organic and inorganic solvents; it is not attacked by hydrochloric or sulphuric acid; but fuming nitric acid oxidizes it to arsenic and tellurous acids. There is nothing here to show which of these products is a chemical individual, since by the same method, if two elements form a homogeneous series of alloys, an indefinitely large number of each compounds could be made. H. Pélabon found that the f.p. curve, Fig. 29, had a maximum at 362° corresponding with As_2Te_3. This compound forms a mass of long, silver-white needles with a pale yellow tint. According to C. A. Tibbals, sodium telluride precipitates from aq. soln. of arsenic trioxide a brown arsenic telluride contaminated with tellurium. Arsenic telluride was allowed to stand for several hrs. in contact with a conc. soln. of sodium polytelluride. The soln., after filtration, was dark brown in colour and it contained both arsenic and tellurium. This would seem to indicate the existence of telluro-compounds analogous to the

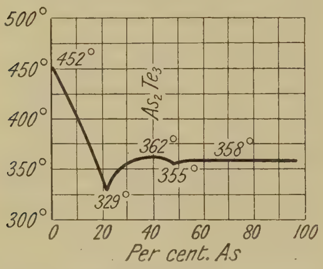

Fig. 29.—Freezing-point Curve of Mixtures of Arsenic and Tellurium.

sulpho-salts. This salt was also prepared by A. Brukl by the action of a feebly acid soln. of arsenic trichloride.

By fusing a mixture of the constituent elements in the correct proportions, A. Oppenheim obtained **antimony telluride**, Sb_2Te_3, as well as SbTe; but as in the case of arsenic, there is nothing to show that chemical individuals were in question. H. Pélabon found a maximum on the f.p. curve corresponding with Sb_2Te_3, and eutectics corresponding with 5Sb : 2Te, and Sb : 10Te. H. Fay and H. E. Ashley also observed a maximum at 629° corresponding with Sb_2Te_3, and a eutectic at 421° corresponding with 87 per cent. Te. The observations of Y. Kimata are summarized in Fig. 30. The maximum at 620° corresponds with Sb_2Te_3; and there are eutectics at 540° with 28 per cent. Te, and at 420° with 89 per cent. Te. There is no indication of the formation of solid soln.; but the flatness of the curve near the eutectic on the bismuth side led H. Fay and H. E. Ashley to assume that solid soln. were formed. N. S. Konstantinoff and V. I. Smirnoff obtained a maximum at 622°, corresponding with Sb_2Te_3, one eutectic at 540° and 30 per cent. Te, and the other at 424° and 89 per cent. Te. They observed no sign of the formation of solid soln. near the antimony end, and only a small region near the antimony telluride. Possibly H. Fay and H. E. Ashley were misled by undercooling phenomena. This salt was also prepared by A. Brukl by the action of hydrogen telluride on a feebly acidic soln. of antimony trichloride. M. Dreifuss made some observations on the properties of these alloys. The measurements of W. Haken on the electrical conductivity of the antimony tellurium alloys are summarized in Fig. 31, and of the thermoelectric power in Fig. 32. M. Padoa observed a maximum in the conductivity corresponding with Sb_2Te_3. E. Becquerel made observations on this subject. The addition of antimony to tellurium causes a rapid decrease in the electrical conductivity and in the thermoelectric power; both quantities pass through a minimum, and then rise rapidly to a maximum corresponding with Sb_2Te_3. The courses of these curves between 0 and 60 per cent. Te are typical of alloys of two crystalline phases forming solid soln. The magnetic susceptibility by H. Endo, and K. Honda and T. Sone is shown in Fig. 30. Between 100 and 62 per cent. Te, the curve is nearly a straight line, and there

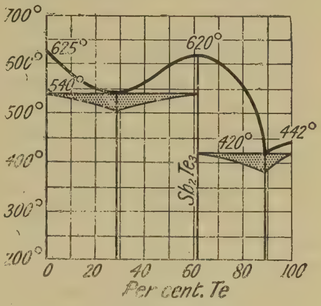

FIG. 30.—Freezing-point Curve of Mixtures of Antimony and Tellurium.

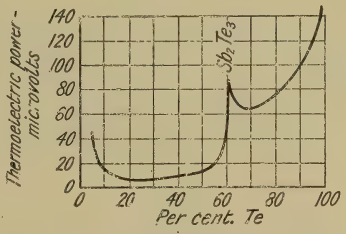

FIG. 32.—Thermoelectric Power of the Sb-Te Alloys.

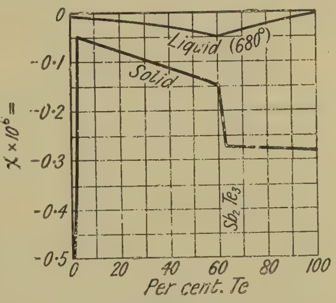

FIG. 33.—Magnetic Susceptibility of the Sb-Te Alloys.

is then a sudden change in the direction of the curve. C. H. Green studied the Sb–Te eutectic.

I. Eques a Born[20] described a mineral from Deutsch-Pilsen, Hungary, which he regarded as a compound of silver and molybdenum, and A. G. Werner called it *Molybdänsilber*. M. H. Klaproth, before his discovery of tellurium, said that it contained only sulphur and bismuth. H. Rose showed that it contains tellurium, bismuth and silver, with traces of selenium and antimony. J. J. Berzelius also showed that the mineral contains tellurium and a little selenium. A similar mineral was found at Riddarhyttan, Sweden, and J. Esmark obtained one from Telemark, Norway. A chemically different mineral was found by A. Wehrle at Schubkau, Schemnitz, and it was called **tetradymite**—from τετράδυμος, fourfold, in allusion to the twinned crystals—J. J. N. Huot called the mineral from Deutsch-Pilsen, Hungary, *wehrlite ;* but since this term had previously been applied to a variety of ilvaite—**6**. 40, 52—G. A. Kenngott proposed the term *pilsenite*. J. J. Berzelius regarded tetradymite as a compound $Bi_2S_3.2Bi_2Te_3$ (that is Bi_2STe_2). G. Rose regarded it as an isomorphous mixture of trigonal telluride and sulphide ; and C. F. Rammelsberg grouped the natural bismuth tellurides, (i) those containing selenide ; (ii) those containing sulphide—*e.g.* tetradymite ; and (iii) those containing both sulphide and selenide—*e.g.* the mineral from San José, Brazil, to which A. Damour applied the term *joséite*. J. F. L. Hausmann had previously applied the term *bornite* to a Brazilian specimen, and F. S. Beudant *bornine* to the specimen from Pilsen. The isomorphism of the bismuth sulphides, selenides, and tellurides was discussed by G. A. Kenngott, C. F. Rammelsberg, J. E. Stead, P. Groth, G. Rose, F. A. Genth, and J. D. Dana. Owing to the variable proportions of the contained tellurium, selenium, and sulphur, tetradymite has been represented by the formula $Bi_2(S,Se,Te)_3$. A. G. Werner called a variety of tetradymite, *Molybdänsilber*, and I. Eques a Born, *argent molybdique*. W. Muthmann and E. C. Schröder applied the term *grünlingite*—after F. Grünling—to a specimen from Carrock Fells, Cumberland ; and S. P. de Rubies, *oruetite* to a specimen from Serrania de Ronda, Spain.

The occurrences in Hungary were described by A. Wehrle, W. Haidinger, V. R. von Zepharovich, W. Muthmann and E. C. Schröder, L. Sipöcz, A. Frenzel, J. C. Döll, K. F. Peters, F. Posepny, and P. Partsch ; in Bohemia, by F. Slavik ; in Silesia, by M. Websky ; in England, by R. P. Greg and W. G. Lettsom, C. F. Rammelsberg, and W. Muthmann and E. C. Schröder ; in Russia, by K. Nenadkevie ; in Norway, by A. Erdmann ; in Sweden, by A. Erdmann, and J. J. Berzelius ; in Canada, by R. A. A. Johnston ; in Virginia, by H. J. Burkart, C. T. Jackson, C. Fisher, and J. D. Dana ; in North Carolina, by F. A. Genth ; in South Carolina, by J. D. Dana ; in Georgia, by H. Credner, F. A. Genth, J. D. Dana, C. T. Jackson, U. Shepard, and D. M. Balch ; in Idaho, by E. V. Shannon ; in Montana, Colorado, Georgia, and Arizona, by F. A. Genth, W. F. Hillebrand, and J. D. Dana ; in Brazil, by J. F. L. Hausmann, F. von Kobell, A. Damour, P. A. Dufrénoy, and F. A. Genth ; in Bolivia, by D. Forbes, and F. A. Genth ; and in New South Wales, by G. W. Card, and J. C. H. Mingaye.

The analyses may be roughly arranged in three groups : (i) those approximating to **bismuth sulphoditelluride,** Bi_2Te_2S, having 51 to 61 per cent. Bi ; 33 to 37 per cent. Te ; 3·6 to 5·1 per cent. S, and up to about 2 per cent. of Se, were analyzed by A. Wehrle, J. J. Berzelius, J. Hauschauer, J. Loczka, W. Muthmann and E. C. Schröder, B. Lightfoot, A. Frenzel, M. N. Short and E. P. Henderson, K. Nenadkevie, S. Koch, C. T. Jackson, F. A. Genth, R. A. A. Johnston, J. C. H. Mingaye, and E. V. Shannon—these include tetradymite, and joséite ; (ii) those occurring in Deutsch-Pilsen, and in North America ; and (iii) those bismuth tellurides which have 78 to 86 per cent. Bi ; 6 to 16 per cent. Te ; 3 to 9 per cent. S ; and up to about 1·5 per cent. Se—*e.g.* joséite, ($Bi_2Te_{3-6}S_6$), analyzed by A. Damour, F. A. Genth, and J. C. H. Mingaye, grünlingite, (Bi_4TeS_3), analyzed by C. F. Rammelsberg, and W. Muthmann and E. C. Schröder, and oruetite, (Bi_2TeS_4), analyzed by S. P. de Rubies. Those which have only a small proportion of sulphur approximate to **bismuth telluride,** Bi_2Te_3, having 50 to 59 per cent. Bi ; 46 to 49 per cent. Te ; and up to about 0·5 per cent. each of Se and S—analyzed by F. A. Genth, D. M. Balch,

W. F. Hillebrand, L. Sipöcz, and A. Wehrle, include wehrlite, pilsenite, and *tellurbismuth.*

J. J. Berzelius observed that when fused, tellurium and bismuth are miscible in all proportions. A. Gutbier, and K. Mönkemeyer formed all the alloys by fusing a mixture of the two elements in an atm. of hydrogen. K. Mönkemeyer found that the f.p. curve, Fig. 34, shows the existence of only one compound, Bi_2Te_3, which appears as a maximum at 573°; there is a eutectic at 261° with 99·08 per cent. Bi, and one at 388°, with 13·91 per cent. Bi. E. Kordes, and C. H. Green studied the Bi–Te eutectic. According to F. Körber and V. Haschimoto, thermal and X-ray analysis show that no compound other than Bi_2Te_3 is formed in the binary system Bi–Te; though there is evidence of the solubility of tellurium in this compound. C. A. Tibbals, and A. Brukl prepared a hydrated bismuth telluride, Bi_2Te_3, by treating a soln. of bismuth acetate with sodium telluride. This telluride is unaffected by hydrochloric acid or sulphuric acid in the cold, but it is decomposed by both when heated in the presence of the air. Nitric acid readily oxidizes it. When heated in hydrogen, the water is first expelled, then the telluride fuses and loses both tellurium and bismuth.

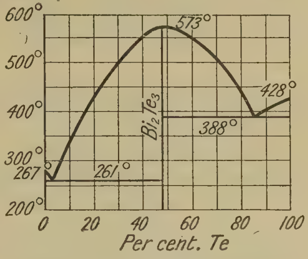

FIG. 34.—Freezing-point Curve of Bi–Te Alloys.

In his study of the tetradymites, M. Amadori investigated the f.p. of the binary system: Bi_2Te_3 and Bi_2S_3. He observed no evidence of the formation of bismuth sulphoditelluride, $2Bi_2Te_3.Bi_2S_3$, analogous to natural tetradymite; but there is a compound, $Bi_2S_3.Bi_2Te_3$—**bismuth trisulphotelluride**—which appears as a maximum at 615° on the f.p. curve, Fig. 35. It forms with bismuth telluride a eutectic at 570° containing 3 molar per cent. Bi_2S_3; and with bismuth sulphide, a eutectic approximating to the composition and f.p. of those of $Bi_2Te_3.Bi_2S_3$. No isomorphous mixtures or solid soln. of bismuth sulphide and telluride were observed, or between $Bi_2Te_3.Bi_2S_3$ and its components. M. Amadori also studied the ternary system: Bi–S–Te comprising the composition of the natural sulphotellurides, that is, Bi–Bi_2Te_3–Bi_2S_3; but no phenomena were observed which could be attributed to the formation of tetradymite, grünlingite, or joséite. The single components Bi,Bi_2S_3, and Bi_2Te_3, and the compound $Bi_2Te_3.Bi_2S_3$, separate from the fused mixtures either in the pure state, or in simple eutectic mixtures; there is no formation of new compounds, and no miscibility relationships between these substances.

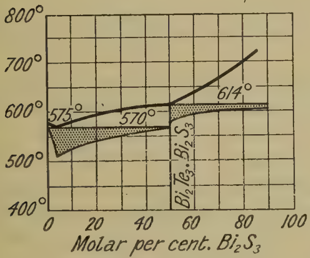

FIG. 35.—The Freezing-point Curve of the Binary System: Bi_2Te_3–Bi_2S_3.

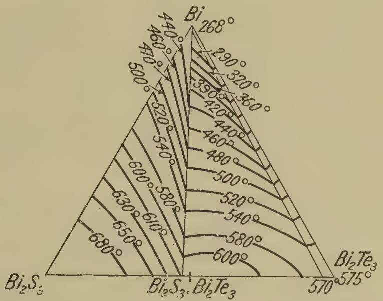

FIG. 36.—Freezing-point Curve in the Ternary System: Bi_2Te_3–Bi_2S_3–Bi.

According to A. Gutbier, the alloys with tellurium in excess are grey and brittle and show a silvery lustre when fractured; and with bismuth in excess, the alloys have a high metallic lustre and are not so brittle. Tetradymite occurs in foliated and granular masses of a steel-grey colour and metallic lustre; it also occurs in small, rarely distinct, trigonal crystals with the axial ratio, according to W. Haidinger, $a : c = 1 : 1·5871$. Twinning occurs about the $(01\bar{1}2)$-plane; and there are also fourlings. The acute trigonal crystals resemble hexagonal prisms; and the trigonal faces may be horizontally striated. The basal cleavage is perfect. The cleavage plates are flexible. W. M. Davy and C. M. Farnham, and M. N. Short and E. P. Henderson studied the etching of polished surfaces of tetradymite. The sp. gr. of the tetradymites range from 7·10 to 7·58; grünlingite, 7·32; oruetite, 7·64 to 7·94; and joséite, 7·92 to 7·94. The hardness is nearly 2. K. Mönkemeyer gave 573° for the m.p. of the artificial telluride; and L. H. Borgström, 593°–602° for the m.p. of natural tetradymite. E. Jannettaz studied the thermal conductivity. J. Joly found that when the mineral is heated, a sublimate of tellurium monoxide occurs between 460° and 480°; and of the dioxide at 750°. A. de Gramont examined the spark spectrum. W. W. Coblentz found that bismuth telluride is not photochemically sensitive. F. Beijerinck, and R. G. Harvey observed that the mineral is an electrical conductor; and W. Haken's measurements of the electrical conductivity of Bi–Te alloys are summarized in Fig. 37. The effect of the formation of the telluride is clearly shown. A. Schrauf and E. S. Dana found that tetradymite in contact with copper is thermoelectrically positive; but grünlingite, and bismuth tellurium from Georgia is negative. W. Haken's observations on the thermoelectric power of alloys of bismuth and tellurium are summarized in Fig. 38. E. Becquerel made observations on this subject. The presence of the telluride is clearly marked. E. T. Wherry said that tetradymite is a poor radio-detector. G. C. Trabacchi's observations, Fig. 39, and H. Endo's, and K. Honda and T. Sone's observations, Fig. 40, on the diamagnetic susceptibility, also show sharp singularities corresponding with the telluride. C. E. Mendenhall and W. F. Lent also made some observations on this subject.

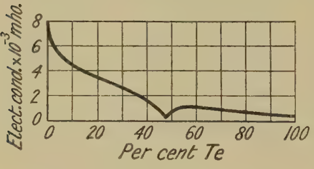

FIG. 37.—Electrical Conductivity of the Bi–Te Alloys.

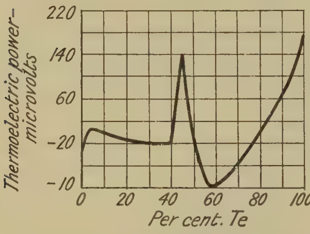

FIG. 38.—Thermoelectric Power of Bi–Te Alloys.

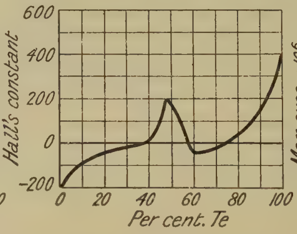

FIG. 39.—Hall's Constant with Bi–Te Alloys.

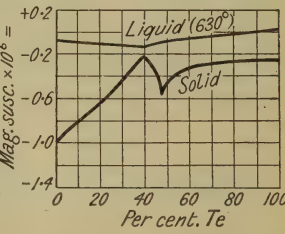

FIG. 40.—Magnetic Susceptibility of Bi–Te Alloys.

A. de Castillo[21] reported a pale steel-grey or lead-grey mineral occurring in granular masses near the Sierra de Tapalpa, Mexico; and it was called **tapalpite.** Analyses were given by C. F. Rammelsberg, and F. A. Genth; they are not very concordant; but the results agree best with the assumption that the mineral is a **silver sulphotellurobismuthite,** $Ag_3Bi(S,Te)_3$. The etching of the polished mineral was studied by W. M. Davy and C. M. Farnham. The mineral has a sp. gr. 7·803; C. F. de Landero gave 7·395. R. G. Harvey measured the electrical resistance. E. Cumenge described a fibrous mineral from the Sierra Blanca, Colorado, and it was named **vondiestite**—after M. von Diest. The analysis corresponds with **silver gold tellurobismuthite,** $(Ag,Au)_5BiTe_4$, of the same type as stephanite, Ag_5SbS_4.

I. Oftedal[22] found that the X-radiogram of **chromium telluride,** CrTe, corresponds with a lattice of the NiAs-type with $a = 2·981$A., $c = 6·211$A., and $a : c = 1 : 1·560$. According to C. A. Tibbals, when sodium telluride reacts with ammonium molybdate or sodium tungstate, dark, strongly coloured soln. are formed which are quite stable in the air. With these soln. hydrochloric acid yields black flocculent precipitates which contain tellurium and either molybdenum or tungsten, as the case may be. This is taken to mean that a **telluromolybdate,** or a **tellurotungstate** is formed. C. H. Weber recommended a trace of tellurium in tungsten incandescent filaments to make them stronger and more flexible. V. M. Goldschmidt discussed the structure of the crystals of **molybdenum ditelluride,** $MoTe_2$, and of **tungsten ditelluride,** WTe_2.

C. A. Tibbals said that **manganese telluride** is formed when sodium telluride acts on manganese acetate in the presence of acetic acid. The light brown precipitate which is first formed rapidly changes to a dark green. If the acetic acid be in excess or if the soln. be hot, the telluride is decomposed with the formation of hydrogen telluride which itself decomposes and deposits tellurium upon the walls of the vessel above the soln. The dark green precipitate is immediately blackened by exposure to air, and dil. acids decompose it very readily with liberation of hydrogen telluride. A. Brukl also prepared this compound. I. Oftedal prepared **manganese monotelluride,** MnTe, and obtained crystals with an X-radiogram corresponding with the NiAs-lattice having $a=4{\cdot}124$ A., $c=6{\cdot}98$ A., and $a:c=1{\cdot}624$; **manganese ditelluride,** $MnTe_2$, was also obtained with crystals having a lattice of the pyrites type with $a=6{\cdot}943$ A. V. M. Goldschmidt discussed the structure of the crystals.

J. J. Berzelius prepared **ferrous telluride,** presumably FeTe, by reducing ferrous tellurite with hydrogen; and J. Margottet, and C. Fabre prepared ferrous telluride by the direct union of the elements in an atm. of an inert gas. L. Moser and K. Ertl made ferrous telluride, as a grey, metallic mass, by passing the vapour of tellurium, under reduced press., over finely-divided iron. It is stable in air. According to G. Tammann and K. Schaarwächter, the two elements begin to react at 435°. I. Oftedal found the composition is not exactly FeTe, and that the X-radiograms correspond with hexagonal cells with $a=3{\cdot}800$ A., and $c=5{\cdot}651$ A. A. Brukl said that ferrous telluride is very sensitive to light, and is decomposed into its elements. Dil. acids furnish hydrogen telluride. J. Margottet, and C. Fabre found that ferrous telluride dissolves in hydrochloric acid with the evolution of hydrogen telluride. C. Fabre gave 15·58 Cals. for the heat of formation of the crystalline telluride. With respect to **ferric telluride,** C. A. Tibbals found that when sodium telluride acts upon a soln. of ferric chloride acidified with acetic acid, a black precipitate is formed which is composed entirely of tellurium. The iron is reduced to the ferrous condition and the soln. contains a large amount of tellurium as the tetrachloride. This is in accord with the fact established by V. Lenher that tellurium is soluble in a soln. of ferric chloride forming ferrous chloride and tellurium tetrachloride. A. Brukl also obtained with ferric salts and hydrogen telluride a precipitate of tellurium and ferrous telluride.

J. Margottet, and C. Fabre prepared **cobalt telluride,** CoTe, by the direct union of the elements in an inert atm.—say nitrogen. W. F. de Jong and H. W. V. Willems found that the X-radiogram of cobalt telluride agrees with a hexagonal lattice having $a=3{\cdot}89$ A., and $c=5{\cdot}36$ A.; and sp. gr. 8·85; I. Oftedal gave $a=3{\cdot}886$ A., $c=5{\cdot}360$ A., and $a:c=1:1{\cdot}380$. J. Margottet, and C. Fabre describe cobalt telluride as a grey, crystalline mass of a metallic lustre; it is not attacked by hydrochloric or sulphuric acid; it changes slowly in moist air; it is oxidized by bromine or bromine water forming cobaltous bromide, hydrobromic acid, and tellurous acid. The heat of formation is 15·30 Cals. C. A. Tibbals observed that when sodium telluride soln. acts upon soln. of cobalt acetate acidulated with acetic acid, a heavy black precipitate is formed which upon analysis shows the composition of **tetrahydrated cobalt hemitritelluride,** $Co_2Te_3, 4H_2O$, corresponding with the sodium telluride, Na_4Te_3. Acids other than nitric have no action upon it in the cold. When heated in an atm. of hydrogen, $Co_2Te_3.4H_2O$, loses water at about 200°, and at a red-heat, tellurium. If the heating is continued until the weight of substance is constant, the residue consists of the normal telluride, CoTe. A. Brukl also prepared this compound.

J. Margottet, and C. Fabre prepared **nickel monotelluride,** NiTe, by heating nickel in the vapour of tellurium; they found it to consist of small reddish crystals with properties like those of the corresponding cobalt telluride. W. F. de Jong and H. W. V. Willems found that the X-radiogram agrees with a hexagonal lattice having a=3·95 A., and c=5·36 A.; and sp. gr. 8·55. I. Oftedal gave a=3·957 A., c=5·354 A., and $a:c$=1 : 1·353. C. Fabre gave for the heat of formation 15·10 Cals.; and W. A. Tilden found the mol. ht. to be—

	100°	200°	300°	400°	500°	600°	700°
Mol. ht. . . .	8·38	11·35	12·41	12·92	13·15	13·28	13·35

According to C. A. Tibbals, sodium telluride precipitates the *tetrahydrate*, $Ni_2Te_3.4H_2O$, from acetic acid soln. of nickel acetate; it is not acted on by cold hydrochloric or sulphuric acid, but is readily oxidized by nitric acid; when heated in hydrogen it loses water and tellurium forming the monotelluride. A. Brukl also prepared this compound.

F. A. Genth[23] described a mineral from Melones Mine, Calaveras Co., California, and it was called **melonite.** W. F. Hillebrand found that it also occurs in Boulder Co., Colorado; and A. Dieseldorff, at Worturpa, South Australia. Analyses, reported by F. A. Genth, and C. F. Rammelsberg, agreed with the formula for *nickel hemitritelluride*, Ni_2Te_3; and those by W. F. Hillebrand, and A. Dieseldorff, with *nickel ditelluride*, $NiTe_2$. A. Dieseldorff gave 7·270 to 7·403 for the sp. gr.; and 1·0 to 1·5 for the hardness. The mineral is reddish-white, and generally occurs in indistinct granular and foliated particles. F. A. Genth thought that it is hexagonal with a marked basal cleavage. W. M. Davy and C. M. Farnham studied the etching of polished surfaces.

N. W. Fischer[24] found that elementary tellurium acts as a reducing agent towards soln. of platinum salts; and F. Rössler, that eq. proportions of platinum and tellurium unite explosively at elevated temp. forming **platinum ditelluride,** $PtTe_2$; and when the ditelluride is fused, **platinum monotelluride,** PtTe, crystallizes out. A. Brukl also obtained the ditelluride by the action of sodium telluride on platinum tetrachloride. According to C. A. Tibbals, a soln. of sodium telluride, acting upon a soln. containing platinum tetrachloride in excess, produces a heavy black precipitate, which is composed entirely of platinum. The tellurium is found in the soln. The reaction may be expressed by the equation, $2Na_2Te+3PtCl_4=4NaCl+2TeCl_4+3Pt$. L. Thomassen observed that platinum ditelluride has crystals of the cadmium iodide type with a space-lattice having a=4·010 A., and c=5·118 A. V. M. Goldschmidt discussed the structure of the crystals. N. W. Fischer found that tellurium acts as a reducing agent toward palladium soln. in a manner analogous to its action upon silver, gold and platinum soln. Sodium telluride precipitates from sodium palladous chloride soln. a very finely-divided black precipitate of **palladous telluride.** This substance is not acted upon by hydrochloric or sulphuric acids in the cold, but is oxidized by nitric acid and very readily dissolved by aqua regia. A. Brukl said that platinum ditelluride is soluble in soln. of sodium and ammonium tellurides, and sparingly soluble in soln. of ammonium and sodium sulphides; it is stable towards hydrochloric acid; nitric acid dissolves all the tellurium and a part of the platinum. It decomposes easily into its elements. A. Brukl obtained **palladium telluride,** PdTe, by the action of sodium telluride on a soln. of palladous chloride, hydrogen telluride reduces the salt to metal. The black telluride is not attacked by dil. acids, but nitric acid oxidizes it readily. L. Thomassen found that the crystals of the monotelluride are of the nickel arsenide type with a space-lattice having a=4·127 A., and c=5·663 A. He also prepared **palladium ditelluride,** $PdTe_2$, in crystals of the cadmium iodide type having a space-lattice with a=4·028 A., and c=5·118 A. The crystals of **ruthenium ditelluride,** $RuTe_2$, are of the pyrites type having a space-lattice with a=6·360 A., whilst a product of the composition of **ruthenium monotelluride,** RuTe, was found to be a mixture of the ditelluride and the metal. Similarly, **osmium ditelluride,** $OsTe_2$, which has crystals of the pyrite type, having the lattice parameter a=6·369 A.; and a product with the composition of **osmium monotelluride,** OsTe, is really a mixture of the ditelluride and metal. None of the compounds showed any evidence of ferromagnetism. V. M. Goldschmidt discussed the structure of these ditellurides.

§ 8. Tellurium Monoxide and Dioxide

J. J. Berzelius[1] attempted to prepare **tellurium monoxide,** TeO, by heating a mixture of tellurium and tellurium dioxide, and by the action of dry sodium carbonate on tellurium dichloride, but without success. E. Divers and M. Shimose said that it is produced when tellurium sulphotrioxide is heated between 180° and 230° in vacuo: $TeSO_3=TeO+SO_2$, and the product washed with a dil. soln. of sodium carbonate to separate the unchanged sulphotrioxide. W. Prandtl and

P. Borinsky, and J. J. Doolan and J. R. Partington prepared the monoxide in a similar way. A little monoxide was also found by E. Divers and M. Shimose to be produced when tellurium sulphotrioxide is decomposed with a small proportion of water; and by pouring a red soln. of tellurium in sulphuric acid into a large proportion of water. Tellurium monoxide is described as a brown, porous, friable mass, which is black tinged with brown, and when rubbed with a burnisher acquires a graphitic lustre. It is stable in dry air, but decomposes when heated in vacuo into tellurium and tellurium dioxide. It is oxidized to the dioxide in moist air, but water has no action. Cold dil. acids decompose it slowly; with hot, conc. hydrochloric acid, it forms tellurium and its dioxide. Hydrogen chloride is absorbed by the monoxide without appreciable change, but when the product is heated, it melts and gives off tellurium dichloride. Sulphur dioxide reduces it slowly to tellurium; it is not altered by liquid sulphur trioxide—even when boiling; and with conc. sulphuric acid it forms a red soln. from which tellurium sulphate crystallizes: $2TeO+3H_2SO_4=Te(SO_4)_2+TeSO_3+3H_2O$. The monoxide is quickly oxidized by nitric acid, and other oxidizing agents in acidic soln., but less easily by neutral or alkaline soln. Potassium permanganate is reduced to manganate. Cold potash-lye acts slowly, but the boiling lye decomposes the monoxide with the separation of tellurium. No compounds with the monoxide—*hypotellurites*—have been prepared, and neither basic nor acidic properties could be assigned to it. W. Damiens said that the alleged monoxide is a mixture of tellurium and tellurium dioxide.

J. J. Berzelius[2] prepared **tellurium dioxide,** TeO_2, by burning tellurium in air; and by the action of nitric acid and hot sulphuric acid on tellurium. According to D. Klein and J. Morel, pulverulent tellurium, obtained by precipitation with sulphurous acid, dissolves readily in dil. nitric acid, with the evolution of nitrogen oxides. The temp. at which soln. takes place is lower the higher the conc. of the acid; with acid of sp. gr. 1·25 the action begins at −10°, *vide supra,* tellurium. At a low temp. soln. is not complete, and a greyish, curdy residue is left, which afterwards turns white, and forms long flexible microscopic needles containing both nitric and telluric acids.

J. J. Berzelius observed that hydrated tellurium dioxide or tellurous acid is precipitated if a soln. of tellurium in cold, dil. nitric acid is poured into cold water. A. Gutbier added that the nitric acid soln. should first be neutralized with ammonium carbonate before the dilution, and the white flocculent precipitate washed with hot water until freed from ammonia. D. Klein and J. Morel observed that when the soln. of tellurium in nitric acid is diluted with water, it deposits hydrated tellurium dioxide or tellurium dioxide, a certain quantity of a basic tellurium nitrate always remaining in soln. Hydrated tellurium dioxide contaminated with half a per cent. of nitric acid is formed when the nitric acid is dil., say of sp. gr. 1·1–1·2, and the action takes place at a low temp. It is a white, curdy substance which gradually changes to a yellowish-white mass of microscopic rectangular lamellæ of tellurium dioxide. When the reaction takes place at a higher temp., or if nitric acid is used, tellurium dioxide is formed in microscopic quadratic octahedra. The nitric acid soln. spontaneously deposits octahedral crystals of tellurium dioxide, and if the nitric acid employed is somewhat dil., say of sp. gr. 1·2, and the temp. has not risen above 30° during the reaction, the precipitation of tellurium dioxide is accelerated by heat. Under these conditions, about half the tellurium dioxide remains in soln. in the form of nitrate, which crystallizes out when the liquid is conc. and cooled.

J. J. Berzelius found that if a soln. of tellurium in warm conc. nitric acid be allowed to stand for some time it deposits tellurium dioxide contaminated with about half a per cent. of nitric acid which is expelled with feeble decrepitation when gently heated. J. J. Berzelius, H. L. Wills, C. Jena, and D. Klein and J. Morel obtained the dioxide by evaporating a soln. of tellurium in nitric acid to dryness, and heating the residue to dull redness; H. Rose said that a temp. of 200° is sufficient; and B. Brauner, 400°. A. Gutbier said that the nitric acid is all expelled only at a temp. at which some tellurium dioxide is volatilized. A. Oppenheim obtained crystals of the dioxide by adding alcohol to the nitric acid soln. of tellurium. N. W. Fischer heated a soln. of tellurium in conc. sulphuric acid until it was decolorized, and obtained on cooling what he regarded as an easily soluble sulphate; and J. J. Berzelius, B. Brauner, and D. Klein and J. Morel obtained a basic sulphate from a soln. of tellurium in hot, conc. sulphuric acid; with 20 per cent. sulphuric acid, tellurium dioxide is formed. D. Klein and J. Morel observed that both the basic sulphate and the basic nitrate are decomposed into tellurium dioxide and acid when washed with hot water. J. J. Berzelius, and A. Oppenheim also obtained the dioxide by pouring a boiling soln. of tellurium tetrachloride into hot water. J. J. Berzelius, and L. Staudenmaier obtained the dioxide by heating telluric acid.

Tellurium dioxide has been analyzed by J. J. Berzelius, H. L. Wills, B. Brauner, L. Staudenmaier, A. Gutbier, and others indicated in connection with the at. wt. of tellurium. The results agree with the empirical formula TeO_2. H. Remy discussed the structure of tellurous acid, H_2TeO_3. A. Brezina said that it is probable that an earth described by J. Esmark in 1798 was native tellurium dioxide; W. Petz also described a yellowish-white earth from Faczebaja which behaved like tellurium dioxide. The mineral was called **tellurite** by J. Nicol, and *tellurium ochre* by C. F. Rammelsberg. The mineral at Zalathna, and Faczebaja, Transylvania, was described by V. von Zepharovich, J. Esmark, and J. A. Krenner; and the occurrence in Colorado, and South Dakota, by F. A. Genth, F. C. Knight, and R. Pearce. W. P. Headden described an occurrence of tellurium dioxide as a white coating on the native tellurium of the Goodhope Mine, Colorado, and also as brownish-yellow, granular masses of small crystals—thought to be tetragonal. The mineral contained 78·68 per cent. of tellurium; a trace of bismuth oxide; 0·79 per cent. of ferric oxide; and 1·04 per cent. insoluble matter.

The hydrated forms of tellurium dioxide, indicated above, are supposed to be **tellurous acid,** H_2TeO_3. J. J. Berzelius prepared the acid by fusing tellurium dioxide with an equal weight of potassium carbonate, dissolving the resulting potassium tellurite in cold water, adding a scarcely perceptible excess of nitric acid; allowing the mixture to stand for some time with frequent stirring; washing the product with ice-cold water; and drying the acid in air at 12°. A solution of tellurium dioxide in potash-lye can be treated in a similar way. The preparation of the acid was also described by R. Schumann. G. O. Oberhelman and P. E. Browning described the preparation of the acid from the residues obtained in the electrolytic refining of copper.

Tellurium dioxide forms small, colourless, octahedral **crystals**; that prepared in the wet-way dries milk-white; and that obtained by slowly cooling the molten dioxide, or by pouring the liquid from the partly solidified portion furnishes needle-like crystals which, according to D. Klein and J. Morel, are probably rhombic; or, according to K. Vrba, possibly monoclinic. A. Brezina, and D. Klein and J. Morel gave for the axial ratios of the rhombic bipyramidal crystals $a:b:c=0·4566:1:0·4693$. The crystals obtained from the nitric acid soln. are, according to D. Klein and J. Morel, tetragonal, and have the axial ratio $a:c=1:1·1076$; and they appear like octahedral, doubly refracting crystals. The crystals were also described by V. M. Goldschmidt. The X-radiogram shows that the space-lattice is of the rutile type with $a=4·79$ A., and $c=3·77$ A., so that $a:c=1:0·788$. L. Pauling discussed the lattice-structure. A. Weller showed that the dioxide is an example of a colourless solid giving a coloured vapour and liquid. The hydrated oxide, or tellurous acid, appears like an earthy powder. D. Klein gave for the **specific gravity** of tetragonal tellurium oxide 5·67 at 15° to 19°; 5·68 for that obtained by heating the nitrate below 350°; and K. Vrba, 5·90 for the tetragonal crystals. For the rhombic form prepared from the fused dioxide, D. Klein gave 5·91 at 0°, and 5·88 at 12°; A. Schafarik, 5·93 at 20°; and F. W. Clarke, 5·75 at 12·5°, and 5·784 at 14°. J. J. Berzelius, and H. Rose found that when the dioxide is heated it becomes pale-yellow, and the colour darkens as the temp. rises. It begins to fuse at a dull red-heat forming a dark yellow, transparent liquid which on exposure to air volatilizes with a slight fuming. As the mass cools it solidifies and evolves enough heat to raise the temp. to dull redness. The white, crystalline mass is translucent when slowly cooled; it readily separates to a crystalline mass which is very easily broken into crystalline fragments. Single drops solidify to a transparent glass. It volatilizes and sublimes at a higher temp. than that at which the metal sublimes; and it can be melted in a crucible without much loss. B. Brauner said that a perceptible volatilization occurs at 400° or 500°. J. J. Berzelius found that at 40°, or even at a lower temp., the hydrated dioxide is resolved into the anhydrous dioxide; hence, a turbid mixture of the hydrated dioxide and water, becomes clear at this temp. as the granules of hydrated dioxide pass into crystals of the anhydrous dioxide. W. G. Mixter gave for the **heat of formation** $(Te,O_2)=87{\cdot}1$ Cals. R. Schumann gave −64320 to 77700 cals. for the free energy of tellurium dioxide at 25°. J. Papish observed that the vapour of tellurium introduced into a bunsen flame colours the flame blue tinged with green in its uppermost part, and a bright, metallic mirror is deposited on a cold surface held in the hottest part of the flame. The reduction of the oxides in the flame is supposed to be the cause of the characteristic luminescence. E. Blanc gave for the two **ionization constants** of tellurous acid, $K_1=2\times10^{-3}$, and $K_2=1\times10^{-8}$. R. A. Schuhmann gave for the e.m.f. of cells of the type $Te \mid TeO_2, HClO_4 \mid H_2$ −0·5286 volt at 25° and −0·5213 volt at 45°. J. J. Kasarnowsky found the conc. of tellurous ions in soln. containing increasing proportions of hydrochloric acid increases as the fourth power of the $H^{\cdot}$-ions, showing that tellurous acid acts as a weak base, $K=[Te^{\cdot\cdot\cdot\cdot}][OH']^4/[H_2TeO_3]$; or $K=1{\cdot}5\times10^{-46}$. According to A. Simek and H. Kadlocva, drops of fused tellurium dioxide on a platinum surface heated by a direct current at 800° to 950° move from the negative to the positive pole. The movement is accompanied by a deformation of the drops, the curvature of the side facing the negative pole being less than that of the other side. Under given conditions, the velocity increases as the drops become larger, but does so less rapidly than the weight of the drops. The velocity of movement and the force by which the drops are driven are both roughly proportional to the current intensity up to a certain limit. If tellurium dioxide is added to drops of fused sodium sulphate, chloride, tungstate, or pyrophosphate, the previously flattened drops become much more spherical and, under the influence of a direct current, move more rapidly than pure tellurium dioxide, a velocity of 16 cms. per sec. being sometimes attained. The direction of motion depends on the conc. of tellurium dioxide and may be reversed as the latter gradually evaporates. The phenomenon is due to changes of interfacial tension caused by potential differences. As previously indicated, the electrolysis of acidic soln. of tellurium dioxide was found by J. C. Poggendorff, L. Schucht, C. Whitehead, E. Müller, etc., to result in the deposition of black tellurium. S. Meyer gave $-0{\cdot}11\times10^{-6}$ mass unit for the **magnetic susceptibility** of tellurium dioxide, and $-0{\cdot}19\times10^{-6}$ mass unit for tellurous acid, and S. S. Bhatnagar and C. L. Dhawan, $-33{\cdot}72\times10^{-6}$ for tellurous acid, and the subject was discussed by S. S. Bhatnagar and S. L. Lather.

L. Staudenmaier found that when tellurium dioxide is heated in a current of **hydrogen,** it is slowly reduced to tellurium, and J. J. Berzelius observed that the alkali tellurites form the tellurides. F. C. Mathers and G. M. Bradbury, and V. Lenher and E. Wolesensky found that the tellurites are oxidized to tellurates when heated in **air.** D. Klein and J. Morel said that tellurium dioxide is sparingly soluble in **water,** and the aq. soln. contains one part of the dioxide in 150,000 parts of water. H. Rose said that the aq. soln. does not redden blue litmus paper; but J. J. Berzelius said that the dioxide reddens litmus after standing some time in contact with the moistened test-paper. The hydrate—tellurous acid—dissolves fairly easily in water forming a soln. which reddens litmus. If heated above 40°, the aq. soln. becomes turbid, and no longer reddens litmus owing to the deposition of fine grains of the anhydrous dioxide. When the aq. solution is evaporated at ordinary temp., it deposits the anhydrous dioxide mixed with a small proportion of the hydrate. J. J. Berzelius said that the aq. soln. of the anhydrous dioxide is tasteless, and that the aq. soln. of the hydrate has a metallic taste. P. Köthner found that **hydrogen dioxide** and **sodium dioxide** oxidize soln. of tellurites to tellurates.

J. J. Berzelius found that aq. soln. of the tellurites are oxidized by **chlorine, bromine,** and **iodine;** and, added B. Brauner, the iodine acts slowly at ordinary temp., and the reaction is complete only at 100°. R. Metzner obtained oxyfluorides by the action of **hydrofluoric acid** on tellurium dioxide; and E. B. R. Prideaux and J. O'Neil Millott, by the action of dry hydrogen fluoride on the dioxide. J. J. Berzelius found the dioxide to be sparingly soluble in most acids, but it is readily dissolved by **hydrochloric acid.** A. Ditte found that tellurium dioxide forms additive compounds with the **hydrogen halides**—*vide infra,* oxyhalides. F. A. Gooch and J. Howland observed that **hydriodic acid** reduces acidic soln. of tellurium dioxide to tellurium. F. A. Gooch and W. C. Morgan found the reaction $H_2TeO_3+4H_2SO_4+4KI=TeI_4+4KHSO_4+3H_2O$ to be quantitative; and K. Someya studied the electrometric titration of tellurous acid under these conditions. R. Schuhmann found the solubility of tellurium dioxide in $0{\cdot}7370M$-, $0{\cdot}2924M$-, and $0{\cdot}1028M$-soln. of **perchloric acid** at 25° to be respectively 5·20, 1·96, and 0·74 gram-atoms $\times 10^3$ per 1000 grms. of water.

H. B. Baker and A. H. Bennett, in their work on the at. wt. of tellurium, heated a mixture of **sulphur** and tellurium dioxide in a current of nitrogen and obtained sulphur dioxide and tellurium. W. Marckwald and A. Foizik showed that a small proportion of the sulphur is also oxidized to sulphur trioxide. According to A. Wehrle, **hydrogen sulphide** and also **ammonium sulphide** produce a black precipitate of tellurium disulphide with soln. of tellurium dioxide—the precipitate is soluble in soln. of ammonium sulphide, hydrogen sulphide, or aq. ammonia. A. Gutbier and F. Flury found that with an aq. soln. of the chloride the precipitate produced in the cold is deep orange-red, and if the soln. is hot, the precipitate is black. R. W. E. MacIvor found that with tellurites, hydrogen sulphide gives a reddish-brown precipitate which rapidly darkens in colour. An excess of **sulphur monochloride** was found by V. Lenher to react with the dioxide in accord with $TeO_2+2S_2Cl_2=TeCl_4+SO_2+3S$; and with an excess of the dioxide: $TeO_2+S_2Cl_2=TeCl_2+2S+O_2$; an excess of **thionyl chloride** forms tellurium tetrachloride, and the dichloride if the tellurium dioxide is in excess. In the cold **sulphuryl chloride** does not react with the dioxide, but when heated in a sealed tube various crystalline products are formed—*e.g.* $TeO_2:SO_2Cl_2=3:4$, $5:9$, $1:2$, and $2:5$—according to the composition of the mixture. The precipitation of tellurium from hydrochloric acid soln. by **sulphur dioxide** has been discussed in connection with selenium—Fig. 2, **10.** 58, 2. E. Divers and M. Shimose observed no reaction between **sulphur trioxide** and tellurium dioxide; B. Brauner found that warm 20 per cent. **sulphuric acid** dissolves about 0·7 per cent. of tellurium dioxide; 30 per cent. acid, about 0·85 per cent.; and 50 per cent. acid, 4·4 per cent. These soln. appear to be supersaturated because after they have stood some time, tellurium dioxide separates from the dil. acid soln., and tellurium sulphate from the conc. acid soln. E. Donath found that **sodium hyposulphite** precipitates tellurium from acid soln. of tellurium, or from soln. of tellurites. F. A. Gooch and J. Howland found that **sodium thiosulphate** is without action on cold acid soln. of tellurium dioxide, but with hot soln., tellurium is precipitated.

J. J. Berzelius said that tellurium dioxide dissolves very slowly in aq. **ammonia;** and H. Rose observed that aq. ammonia precipitates tellurous acid from soln. of tellurium salts, and the precipitate dissolves in an excess of the precipitant when the liquid is warmed. V. Lenher and E. Wolesensky obtained *pentitamminotellurous acid,* $5H_2TeO_3.NH_3$, as an intermediate stage in the decomposition of ammonium tellurite, but it is believed not to be a definite compound. According to C. Whitehead, when a soln. of a tellurite is boiled with **ammonium chloride,** tellurous acid is precipitated; while A. Gutbier and F. Flury found that when tellurium dioxide is heated with ammonium chloride, the mixture becomes yellow and then orange, and a white sublimate of $TeO_2.2HCl$ is formed. The mixture on being further heated, assumes a dark colour with the formation of a yellow sublimate. $TeCl_2.2NH_3$, which blackens on careful heating. Tellurium finally remains as a brittle mass. These phenomena do not occur when ammonium chloride is replaced by ammonium nitrate, carbonate, sulphate, phosphate, acetate, or molybdate. J. J. Berzelius found that tellurium dioxide is freely soluble in **nitric acid**; and D. Klein and J. Morel observed that boiling, dil. nitric acid dissolves some tellurium dioxide; whether or not tellurium dioxide will separate from the soln. depends on the conc. of the acid—*vide supra.* The dioxide is freely soluble in the hot, conc. acid. P. Jannasch and M. Müller, and A. Gutbier observed that acidic or alkaline soln. of tellurium dioxide are reduced to tellurium by **hydrazine salts**; whilst **phenyl hydrazine** violently reduces hydrochloric acid soln. at ordinary temp. with the evolution of heat, and the liberation of nitrogen. J. J. Berzelius found that tellurium is precipitated by **phosphorus** from acid soln. of tellurium dioxide; N. W. Fischer found that tellurium is also precipitated by alcoholic soln. of phosphorus; H. Rose, by **phosphorous acid**; and A. Gutbier, by **hypophosphorous acid.** H. Rose obtained a white precipitate by adding **sodium hydrophosphate.** V. Lenher found that **phosphorus trichloride** reduces tellurium dioxide to the element, **phosphoryl chloride** forms the complex $TeCl_4.POCl_3$; he also found that **arsenic trichloride** reacts with tellurium dioxide forming tellurium tetrachloride and arsenic trioxide. M. H. Klaproth observed that **antimony** reduces a soln. of a tellurous salt to tellurium. J. J. Berzelius, D. Klein, B. Brauner, and F. Becker found that tellurium dioxide replaces antimonyl in **potassium antimonyl tartrate** forming potassium telluryl tartrate. Tellurium dioxide reacts with **antimony trichloride** forming, according to V. Lenher, tellurium tetrachloride and antimony trioxide; **antimony pentachloride** forms the complex $TeCl_2.SbCl_5$.

J. J. Berzelius said that tellurium dioxide is decomposed by **carbon** at a comparatively low temp., and with a kind of detonation; and with alkali tellurites and carbon the alkali telluride is formed. J. J. Berzelius observed that tellurites are decomposed by the **carbon dioxide** of the atm. H. Rose observed that tellurium dioxide is reduced when fused with **potassium cyanide.** H. Rose found that acid soln. of tellurium dioxide gave no precipitate with **potassium ferro-** or **ferricyanide,** with **oxalic acid,** or with **tannin.** F. Stolba, and L. Kastner found that soln. of tellurites are completely reduced to tellurium by boiling with **glucose.** V. Lenher found that **carbon tetrachloride** has no action on tellurium dioxide. A. Oppenheim could not prepare alkyl tellurites. T. R. Glauser recommended tellurium dioxide for combustion analyses for carbon and nitrogen in dealing with aluminium nitride, calcium cyanamide, ferrosilicon, ferrochrome, hard steels, carborundum, etc. The tellurium dioxide melts to a heavy, mobile liquid in which these substances readily dissolve.

J. J. Berzelius found that copper reduces soln. of tellurium salts to the metal; M. H. Klaproth, and J. Löwe obtained a similar result with **zinc**; N. W. Fischer, with **cadmium,** and **mercury**; M. H. Klaproth, with **tin**; N. W. Fischer, with **lead**; and P. Berthier, and F. Stolba, with **iron.** N. W. Fischer added that the tellurium is usually precipitated as a black powder which by friction acquires a metallic lustre; dendritic tellurium forms when lead is used; the precipitation is usually incomplete; and a basic tellurite or basic tellurate may be formed. J. J. Berzelius found that tellurium dioxide readily dissolves in aq. soln. of **alkali hydroxides**; but in aq. soln. of the **alkali carbonates** only during a prolonged boiling; it readily dissolves when melted with alkali carbonates with the expulsion of carbon dioxide; it dissolves in fused **alkali nitrates** forming tellurates. Tellurous acid readily dissolves in aq. soln. of alkali hydroxides or carbonates, the carbon dioxide escaping only when heat is applied. According to V. Lenher and P. D. Potter, the yellowish-brown substances suspended in the fused mass before the liquid solidifies contain variable proportions of potassium tellurate and tellurium dioxide depending on the time of heating and other conditions.

According to N. W. Fischer, an ammoniacal soln. of **copper oxide** gives a greyish-blue precipitate with tellurous acid or tellurous salts. F. C. Mathers and F. V. Graham observed that **lead dioxide** converts tellurium dioxide into lead tellurate, and that the optimum temp. is 170°. H. Rose found that **barium chloride** gives a white precipitate insoluble in ammonia, but with **calcium chloride** precipitation occurs only after the addition of ammonia. A. Hilger obtained a white precipitate by adding a **magnesium salt** and ammonia to a soln. of a tellurite. N. W. Fischer found that **mercurous nitrate** gives a white precipitate; while **stannous chloride** reduces tellurous salts to tellurium which appears as a black precipitate; if the tellurous salt be very dilute, the stannous chloride produces a brown coloration which is perceptible at a dilution of 1 : 600,000. B. Brauner founded a volumetric process for the determination of tellurium on this reaction. N. W. Fischer found that **lead acetate** soln. gives a white precipitate. V. Lenher found that **lead tetrachloride** reacts with tellurium dioxide forming tellurium tetrachloride. According to B. Brauner, **chromic acid** oxidizes a hydrochloric acid or sulphuric acid soln. of tellurium dioxide to telluric acid. The reaction is slow, but is faster in hydrochloric than in sulphuric acid soln. L. Staudenmaier obtained similar results in nitric acid soln. Tellurium dioxide and the tellurites form complex salts with **molybdates, tungstates,** and **vanadates** (*q.v.*). B. Brauner observed that **potassium permanganate** oxidizes a hydrochloric or sulphuric acid soln. of tellurium dioxide, and in the latter case, with the development of oxygen: $2TeO_2+KMnO_4+4HCl=2TeO_3+MnCl_3+KCl+2H_2O$. F. A. Gooch and J. Howland studied the oxidation of tellurites to tellurates by potassium permanganate. Soln. of tervalent **manganese salts** do not oxidize tellurium dioxide. The reaction was studied by W. T. Schrenk and B. L. Browning. B. Brauner, and V. Lenher and H. F. Wakefield represented the reaction with **potassium dichromate**: $3TeO_2+K_2Cr_2O_7+8HCl=3H_2TeO_4+2KCl+2CrCl_3+H_2O$.

§ 9. The Tellurites

Tellurous acid is dibasic forming normal *tellurites*, R_2TeO_3, and *hydrotellurites*, $HTeO_3$; as well as salts of the hypothetical *pyrotellurous acid*, $H_2Te_2O_5$; *tetratellurous acid*, $H_2Te_4O_9$; and *hexatellurous acid*, $H_2Te_6O_{13}$.

F. A. Flückiger [1] heated tellurium with aq. ammonia in a sealed tube and obtained what he regarded as **ammonium tellurite.** According to J. J. Berzelius, tellurium dioxide dissolves very slowly in aq. ammonia, while tellurous acid dissolves very quickly. On evaporating the soln. at a gentle heat, it gives off ammonia ; leaving tellurous acid contaminated with a 0·41 per cent. of ammonia. V. Lenher and E. Wolesensky said that ammonium tellurite probably exists in soln. and also in the solid state when surrounded by a sat. soln. of tellurous acid in ammonia, but on attempting to isolate it, it decomposes spontaneously at ordinary temp. forming tellurous acid, etc. They dissolved tellurium dioxide in aq. ammonia of sp. gr. 0·91, by heating the mixture in sealed tubes at 95°–100° for 10 hrs. After cooling and filtering, the soln. was allowed to evaporate spontaneously, when small crystals were obtained in the form of short needles arranged in radiating groups, or clusters of thin, transparent plates. On drying, these became opaque. They dissolved readily in ammonia, but were insoluble in water. If ammonium chloride be added to a soln. of tellurous acid in aq. ammonia, J. J. Berzelius said that what is probably **ammonium pyrotellurite,** $NH_4HTe_2O_5.12H_2O$, appears as a flocculent precipitate. The same salt is produced by adding ammonium chloride to a soln. of tellurous acid, or tellurium dichloride in warm aq. ammonia, and on adding alcohol, more of the same salt is precipitated. The pyrotellurite is decomposed by heat into ammonia, water, and tellurium dioxide.

J. J. Berzelius obtained normal **lithium tellurite,** Li_2TeO_3, by melting together equimolar proportions of tellurium dioxide and lithium carbonate, and slowly cooling the product. The aq. soln., when evaporated over conc. sulphuric acid, yields a white, earthy mass. Similarly with **lithium pyrotellurite,** $Li_2Te_2O_5$, or **lithium tetratellurite,** $Li_2Te_4O_9.nH_2O$, using the proper proportions of the components. The aq. soln. splits into the normal salt and **lithium hydropyrotellurite,** $LiHTe_2O_5.nH_2O$; the latter is also obtained from a soln. of the pyrotellurite in hot water. When heated, it intumesces as the water is driven off, and it melts as a red-heat is approached, forming a yellow liquid which, on cooling, produces a transparent glass, which behaves towards hot water like the pyrotellurite. Hot water breaks down the hydropyrotellurite forming a precipitate of tellurous acid, while a more acid tellurite passes into soln.; with cold water the crystals of tellurous acid pass into the gelatinous state, but still retain the external form of the crystals.

J. J. Berzelius prepared normal **sodium tellurite,** Na_2TeO_3, as in the case of the lithium salt, by fusing equimolar proportions of tellurium dioxide and sodium carbonate; during solidification the tellurite furnishes crystals which, according to C. F. Rammelsberg, are rhombic prisms with angles 113° to 114°. J. J. Berzelius said that the salt dissolves slowly but completely in cold water, and more quickly in hot water, from which it does not separate on cooling. Alcohol precipitates from the aq. soln. a conc. liquid which, in a few days, deposits crystals of hydrated salt. When the aq. soln. is evaporated, C. F. Rammelsberg found that rhombic prisms of the *pentahydrate,* $Na_2TeO_3.5H_2O$, are formed which lose their water at 120°. V. Lenher and E. Wolesensky also prepared this salt. They found that if to a conc. soln. of sodium tellurite about twice its vol. of 95 per cent. alcohol be added, the two liquids do not mix. There is, however, a redistribution of the water between the alcohol and the tellurite. The alcoholic layer increases in vol. by abstracting water from the tellurite soln., while the latter becomes more conc. Long standing and repeated shaking will not produce any further changes in this system. If, now, solid sodium tellurite be added, it will slowly dissolve, increasing the vol. of the tellurite soln., and withdrawing water from the alcoholic layer. But if, instead, about five vols. of absolute alcohol be added, the water is almost completely withdrawn from the sodium tellurite, and the latter is precipitated. C. Jena regarded the salt as a *hemienneahydrate,* $Na_2TeO_3.5\frac{1}{2}H_2O$. E. Blanc found that the percentage degree of hydrolysis of $0·0075N$-soln. of sodium tellurite is 0·773; and of $0·0073N$- sodium hydrotellurite, 0·0022. J. J. Berzelius prepared sodium **pyrotellurite,** $Na_2Te_2O_5$, by the fusion process as in the case of the **sodium** salt; the boiling aq. soln., when slowly cooled, furnishes pearly scales and thin six-sided plates of **sodium hydropyrotellurite,** $NaHTe_2O_5.2H_2O$, or **sodium tetratellurite,** $Na_2Te_4O_9.4H_2O$, and C. F. Rammelsberg found that the crystals lose half their water when exposed to air. V. Lenher and E. Wolesensky also prepared the pyro- and tetratellurites. They found that the pyrotellurite was oxidized by heating it for five days in air, and the tetratellurite and tellurium dioxide not at all. Hence as the proportion of tellurium dioxide in the tellurite increases, the tendency to oxidize in air decreases. According to C. F. Rammelsberg, if the normal tellurite be treated with hot water, a white crystalline powder of **sodium tritellurite,** $Na_2Te_3O_7.5H_2O$, is formed; it loses half its water at 120°, and the rest when melted. The brown, molten salt forms a transparent yellow glass when cold. By treating a soln. of the normal salt with as much nitric acid as is possible without making the liquid react acid, a precipitate of **sodium hexatellurite,** $Na_2Te_6O_{13}.8H_2O$, is formed; it is washed with cold water, and dried in air. It loses all its combined water on fusion.

J. J. Berzelius prepared normal **potassium tellurite,** K_2TeO_3, by the fusion process as in the case of the lithium and sodium salts. The white product consists of crystals with an alkaline reaction and caustic taste. V. Lenher and E. Wolesensky found that it is well to conduct the fusion in an inert atm.—say, carbon dioxide—to prevent the oxidation of tellurite to tellurate. The white, crystalline mass is deliquescent, and extremely soluble in water. The aq. soln. slowly deposits tellurous acid on exposure to air, and more readily when air is bubbled through the soln. On heating, however, the precipitate again dissolves, showing that at higher temp. tellurous acid will displace carbonic acid. When heated in air between 460°–470°, the tellurite is slowly oxidized. Thus 35·09 per cent. was converted to tellurate in 10 hrs., and 99·49 per cent. in 50 hrs. It dissolves slowly in cold water, but more rapidly in hot water; and the evaporation of the aq. soln. over sulphuric acid furnishes a syrupy mass which afterwards solidifies into a granular, non-deliquescent mass. V. Lenher and E. Wolesenky showed that potassium tellurite cannot be crystallized from aq. soln., for the aq. soln. when evaporated over sulphuric acid and solid potassium hydroxide furnishes a hard, transparent, waxy or resinous-looking homogeneous mass of the *trihydrate*, $K_2TeO_3.3H_2O$. This compound was also prepared by treating tellurium dioxide with a soln. of caustic potash, either cold or hot. The combination seems to take place only in the proportion of $2KOH : TeO_2$, so that if more than this proportion of tellurium dioxide be present, some will remain undissolved. Tellurium dioxide dissolves in hot soln. of potassium carbonate, although not so readily as in potassium hydroxide. The action of alcohol on potassium tellurite resembles its action on the sodium salt (*q.v.*). If molar proportions of the components be fused together, **potassium pyrotellurite,** $K_2Te_2O_3$, is formed as a colourless, translucent, crystalline mass; when heated in air between 460° and 470°, 26·88 per cent. was converted into tellurite in 10 hrs., and 99·47 per cent. in 57 hrs. At a rather higher temp., the tellurate loses oxygen and is reduced to tellurite, so that between 450° and red-heat, there is the reversible reaction $2K_2TeO_3+O_2\rightleftharpoons 2K_2TeO_4$. The aq. soln. is resolved by cold water into the normal tellurite which dissolves, and hydropyrotellurite which remains undissolved. Boiling water dissolves it completely, but on cooling deposits grains of the hydropyrotellurite; if the hot water also holds pyrotellurite in soln., the liquid when evaporated on the water-bath deposits the pyrotellurite as a hard, crystalline mass. If powdered tellurous acid be boiled with a soln. of potassium carbonate, the hot, filtered liquid deposits **potassium hydropyrotellurite,** $KHTe_2O_5.1\frac{1}{2}H_2O$, or **potassium tetratellurite,** $K_2Te_4O_9.4H_2O$, in regular six-sided prisms and plates; the mother-liquid yields more of the salt on evaporation and cooling; and the remaining liquid contains the normal salt in soln. The action of cold water and heat are the same as in the case of the lithium salt (*q.v.*). V. Lenher and E. Wolesensky found that the oxidation of the pyro- and tetra-tellurites in air resembles the cases with the corresponding sodium salts. According to D. Klein, if a soln. of a mol of oxalic acid, and 2 mols of potassium tellurite be mixed, and the precipitate be washed with water, and dried at 100°, **potassium hexatellurite,** $K_2Te_6O_{13}.2H_2O$, is formed as a white, amorphous powder, which melts at a dull red-heat giving off water. The heated salt may blacken owing to the reducing action of a trace of oxalic acid. It is not decomposed by water in which it is sparingly soluble.

According to J. J. Berzelius, a siskin-green precipitate of **copper tellurite** is formed by double decomposition. It is insoluble in water; turns black and gives off water when heated; readily fuses and solidifies on cooling to form a black mass with a conchoidal fraction. It is reduced on charcoal before the blow-pipe to form copper telluride. P. E. Browning and G. O. Oberhelman found that by evaporating an ammoniacal soln. of tellurous acid containing some copper salt over sulphuric acid in the presence of soda-lime, **ammonium copper tellurite,** approximating $5NH_3.CuO.9TeO_2.6H_2O$, is formed; the same salt is obtained by mixing slowly with constant stirring an ammoniacal soln. of tellurous acid and copper chloride.

J. J. Berzelius obtained **silver tellurite,** Ag_2TeO_3, by double decomposition—say from sodium tellurite and silver nitrate. It appears as a yellowish-white precipitate, soluble in ammonia. The ammoniacal soln., on evaporation, yields a basic salt. R. D. Hall and V. Lenher said that the pale yellow powder, dried at 105°, is stable in light. V. Lenher and E. Wolesensky found that the precipitate is pale yellow only when an excess of silver nitrate is used; if the sodium tellurite is in excess, the precipitate is white. When dried, both precipitates are buff-coloured, and have the same composition, but on standing, the one which was precipitated in presence of an excess of silver nitrate begins to turn dark in colour, and in the course of a week or two changes completely to a dark bluish-grey colour. The other does not change, and has actually been kept for twenty months without undergoing any modification. When silver tellurite is heated to 250° it becomes deep blue or purple in colour. This change takes place without any change in weight. On heating still higher, to 450° or 500°, it again changes to a pale yellow. In this last condition it can be cooled down to ordinary temp. unchanged, provided it is not disturbed during the cooling. But if during this cooling, and while it is still quite hot, it is disturbed by compression with a glass rod, the mass immediately changes to the purple variety. Again, when freshly precipitated silver tellurite is treated with ammonium hydroxide it dissolves immediately, and when the soln. is allowed to evaporate spontaneously brownish-yellow crystals deposit. These crystals contain neither ammonia nor water, and can be heated to 500° or higher without any change in weight. On cooling, after being thus heated, these crystals again yield the ordinary pale yellow silver tellurite. It thus appears that silver tellurite can exist in a number of different varieties. The freshly-precipitated salt is soluble in acetic and tartaric acids, also in nitric and sulphuric acids. Hydrochloric acid decomposes it with the formation of silver chloride and tellurium tetrachloride. It is insoluble in water. The precipitated tellurites have little tendency to assume the crystalline state; and no crystallization was observed by allowing precipitated silver tellurite to stand in contact with acidulated water. G. Rose obtained what is supposed to have been **silver pyrotellurite** from a soln. of silver telluride in nitric acid. The small, acuminated square prisms have an adamantine lustre; and are insoluble in water.

J. J. Berzelius obtained **calcium tellurite,** $CaTeO_3$, by heating a mixture of equimolar parts of the component oxides; the mass does not fuse at 960°; by treating alkali tellurite soln. with a calcium salt, white flecks of calcium tellurite are formed, which are sparingly soluble in cold water, and easily soluble in hot water. The evaporation of the aq. soln. gives a white earthy product of hydrolysis. **Strontium tellurite,** $SrTeO_3$, was obtained, likewise also **barium tellurite,** $BaTeO_3$. C. F. Rammelsberg also prepared the barium salt. V. Lenher and E. Wolesensky found that the white flocculent precipitate is obtained by mixing soln. of sodium tellurite and barium chloride, but it could not be obtained in the crystalline state. All the precipitates, even those obtained in dil. soln., contained chlorine which could not be washed out. The analyses ranged from $8BaTeO_3.5BaCl_2.4H_2O$ to $20BaTeO_3.\frac{1}{2}BaCl_2.20H_2O$. If a mixture of the component oxides in the theoretical proportions be heated to redness, J. J. Berzelius found that **calcium pyrotellurite,** $CaTe_2O_5$, is obtained in micaceous scales; and he found that under analogous conditions, using the theoretical proportions of the constituents, **barium tetratellurite,** $BaTe_4O_9$, could be prepared. The product appears as a transparent, colourless glass. If an aq. soln. of barium tellurite be treated with dil. nitric acid, a voluminous precipitate of the hydrate, $BaTe_4O_9.H_2O$, or **barium hydropyrotellurite,** $Ba(HTe_2O_5)_2$, is formed. It dissolves in an excess of warm nitric acid, and on evaporation of the soln., tellurium dioxide is first deposited.

According to J. J. Berzelius, white voluminous flakes of **beryllium tellurite** are produced when a soluble tellurite is added to a soln. of a beryllium salt; and **magnesium tellurite** is formed in an analogous way. V. Lenher and E. Wolesensky found that the salt is the *pentitaenneahydrate,* $5MgTeO_3.9H_2O$; and that it is only sparingly soluble, but even then it is much more soluble than the corresponding salt of the alkaline earths. The precipitate becomes granular when allowed to stand in contact with the mother-liquor. It does not vary in composition with the proportions of the salts used in its formation. When heated at different temp. to a constant weight, these results, Fig. 41, show that at about 450°, there are two phases, below that temp. the pentitaenneahydrate is stable, and above that temp., the *decitaenneahydrate,* $10MgTeO_3.9H_2O$. J. J. Berzelius obtained a white, flocculent precipitate of **zinc tellurite** by double decomposition. A. Oppenheim prepared **cadmium tellurite** as a white, gelatinous precipitate, by adding sodium tellurite to a soln. of cadmium nitrate. It dissolves in nitric acid forming a colourless soln., and in hydrochloric acid forming a yellow soln. V. Lenher and E. Wolesensky used soln. of cadmium chloride and sodium tellurite. The precipitate approximates in composition the normal tellurite, $CdTeO_3$. J. J. Berzelius obtained **mercurous tellurite** as a dark yellow precipitate which becomes brown on exposure to air, and forms **mercuric tellurite** which is also obtained by double decomposition of a soluble tellurite and a mercuric salt.

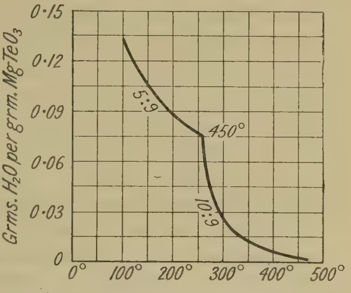

Fig. 41.—Dehydration Curve of Hydrated Magnesium Tellurite.

J. J. Berzelius reported **aluminium tellurite** to be formed as a white, flocculent precipitate on adding sodium tellurite to a soln. of an aluminium salt; it is insoluble in an excess of the aluminium salt soln. He also obtained **yttrium tellurite** in an analogous manner; and it is insoluble in an excess of the yttrium salt soln. White **zirconium tellurite** was obtained in an analogous manner; and likewise also **thorium tellurite.** J. J. Berzelius found that a basic **lead tellurite** is precipitated by the action of potassium tellurite on a soln. of lead acetate; and a white, flocculent precipitate of normal lead tellurite was also obtained; V. Lenher and E. Wolesensky mixed soln. of lead nitrate and sodium tellurite, and found that the precipitate is the tritadihydrate, $3PbTeO_3.2H_2O$. It is soluble in acids, and when heated forms the yellow, anhydrous salt; and it melts to form, on cooling, a transparent glass. It is reduced to telluride when heated with carbon. V. Lenher and E. Wolesensky found that in air at 440°–470° it oxidizes more slowly than sodium tellurite.

According to W. A. A. Prandtl, if a hydrochloric acid soln. of tellurous acid be mixed with a soln. of sodium vanadate, or if sodium tellurite and vanadate be mixed with hydrochloric acid, an orange-yellow, amorphous precipitate is produced and it rapidly dissolves if the liquor is acidic or alkaline; but if neutral a hydrated **sodium telluritovanadate** is formed. The precipitate is decomposed by water, and vanadic acid passes into soln. while tellurous acid remains undissolved. The composition of the precipitate varies with the conc. of the vanadic acid in the mother-liquor. From strongly alkaline, hot, conc. soln. of sodium tellurite and vanadate, with the former in excess, white needles of a complex salt separate out as the liquid cools. It is completely decomposed into its components when recrystallization is attempted. C. Jena treated sodium vanadate, in neutral or acidic soln., with tellurium tetrachloride, and obtained a series of complex salts. If the vanadate and tellurium tetrachloride in hydrochloric acid soln. be in the proportion $V_2O_5 : TeO_2 = 2 : 1$, and the soln. neutralized with sodium hydroxide, the complex **sodium tetravanadatopentatellurite,** $Na_2O.2V_2O_5.5TeO_2.2H_2O$, is formed; if in the proportion 1 : 1, the complex **sodium tetravanadatohexatellurite,** $Na_2O.2V_2O_5.6TeO_2.12H_2O$, when dried at 100° the *dihydrate* is formed, and when dried over sulphuric acid in vacuo, the *trihydrate;* and if the proportion be 1 : 5, **sodium tetravanadatodecatellurite,** $Na_2O.2V_2O_5.10TeO_2.3H_2O$, is formed. By working in alkaline soln., with 20 grms. of tellurium dioxide and 2 grms. of vanadium pentoxide and the mixture neutralized with sodium hydroxide, **sodium hexavanadatotellurite,** $Na_2TeO_3.6Na_3VO_4.20H_2O$, is formed; with 40 grms. of tellurium dioxide and 5 grms. of vanadium pentoxide, **sodium divanadatopentatellurite,** $5Na_2TeO_3.2Na_3VO_4.52H_2O$, is formed; the conc. of the mother-liquor yields what is supposed to be a mixture of **sodium divanadatotetratellurite,** $4Na_2TeO_3.2Na_3VO_4.48H_2O$, and of **sodium divanadatotritellurite,** $3Na_2TeO_3.2Na_3VO_4.44H_2O$.

J. J. Berzelius prepared **chromium tellurite,** as a pale greyish-green precipitate, by adding a soluble tellurite to a soln. of a chromic salt; it is soluble in an excess of the latter. O. W. Gibbs made some preliminary observations on the **tellurito-**

molybdates analogous to the selenomolybdates; and on the **telluritotungstates** analogous to the selenitotungstates. According to D. Klein, tellurous acid dissolves readily in soln. of sodium, ammonium, or potassium paratungstate, yielding in the first case micaceous crystals and a dense mother-liquor. This mother-liquor gives no precipitate with hydrochloric acid in the cold, and is only decomposed after several successive evaporations to dryness with this acid. The mother-liquor contains tellurous acid, which is precipitated only by sulphurous acid or sodium hydrosulphite in the cold, after the addition of hydrochloric acid. The action of tellurous acid on ammonium or potassium paratungstate yields no crystalline products, but only a pulverulent deposit, which contains tungstic and tellurous acids, and behaves like a tungstotellurite. J. J. Berzelius obtained by double decomposition pale lemon-yellow, insoluble **uranyl tellurite.**

J. J. Berzelius, and V. Lenher and E. Wolesensky obtained a white or faintly pink, flocculent precipitate of **manganese tellurite,** by mixing sodium tellurite with a soln. of manganese chloride. The salt is very unstable. On standing, the colour gradually changes to a deep chocolate-brown. The change takes place more rapidly when the mixture is brought into direct contact with air. This change is due to oxidation of the manganese to the tervalent state. When the chocolate-coloured substance is treated with hydrochloric acid, a dark, greenish-brown soln. of manganic chloride is formed. This colour is discharged by diluting the soln. with water, or by boiling; in the latter case chlorine is evolved. If the precipitation is carried out with soln. which have been previously thoroughly boiled to expel the air, the precipitate is perfectly white, and remains so as long as contact with air is avoided. The freshly-precipitated manganese tellurite is more sensitive to oxidation than when it has stood some time. J. J. Berzelius obtained by double decomposition **ferrous tellurite** in yellowish-grey flakes; and **ferric tellurite** in yellow flakes. E. S. Dana and H. L. Wells found greenish-yellow masses or small mamillary forms of a mineral in the El Plombo mine, Tegucigalpa, Honduras; and it was named **durdenite**—after H. S. Durden. The analysis corresponds with the *tetrahydrate*, $Fe_2(TeO_3)_3.4H_2O$. The hardness is 2·0 to 2·5. W. F. Hillebrand also described a yellowish-green hydrated ferric tellurite from Tombstone, Arizona, which occurs in thin scales, probably monoclinic. The (010)-cleavage is perfect. The mineral was called **emmonsite**—after S. F. Emmons. Its exact composition is unknown. The ratios $Fe_2O_3 : TeO_2 : H_2O$ are 3·16 : 1 : 1·77. The hardness is about 5. **Cobalt tellurite** is a dark purple precipitate; V. Lenher and E. Wolesensky found that the precipitate is *monohydrated*, $CoTeO_3.H_2O$, and melts between 300° and 400° without changing colour, but with the loss of its water of crystallization. J. J. Berzelius obtained by double decomposition **nickel tellurite** in pale greenish-white flakes. V. Lenher and E. Wolesensky found that the precipitate is *monohydrated*, $NiTeO_3.H_2O$, and when heated, loses water and turns light brown.

§ 10. Tellurium Trioxide and the Telluric Acids

J. J. Berzelius[1] said that when telluric acid is heated above 360°, but not to a red-heat, **tellurium trioxide,** TeO_3, remains. If the temp. be too high, the trioxide decomposes into the dioxide, when the product instead of being orange-yellow is white. If tellurium dioxide has been formed, it can be dissolved out by means of hydrochloric acid. L. Staudenmaier said that the last traces of water are given off very slowly. Tellurium trioxide obtained in this way is orange-yellow, and the granules retain the form of the crystals of orthotelluric acid from which it was derived. F. W. Clarke said that the sp. gr. is 5·07 at 14·5° ; 5·08 at 10·5° ; and 5·11 at 11°. It decomposes when heated to dull redness, the m.p. of tellurium dioxide, giving off oxygen and forming the dioxide. The trioxide is insoluble in cold and hot water ; cold hydrochloric acid, hot nitric acid, and moderately conc. potash-lye are without action ; hot, conc. hydrochloric acid decomposes it with the evolution of chlorine ; and very conc., hot potash-lye dissolves it with the formation of tellurates.

The tellurium in the trioxide is probably sexivalent like sulphur in sulphur trioxide. The hydrate, $TeO_2.3H_2O$, sometimes regarded as *dihydrated telluric acid,* $H_2TeO_4.2H_2O$, behaves as if it were **orthotelluric acid,** H_6TeO_6 ; while the hydrate, $TeO_2.H_2O$, generally called telluric acid, H_2TeO_4, is **metatelluric acid.** This acid appears as the *dihydrate—i.e.* orthotelluric acid—and the *hexahydrate,* $H_2TeO_4.6H_2O$. F. C. Mathers and F. V. Graham obtained telluric acid by the action of sulphuric acid on lead tellurate ; and F. C. Mathers and G. M. Bradbury, by the action of conc. nitric acid on calcium tellurate. This latter may be the *tetrahydrate of orthotelluric acid,* $H_2TeO_2.4H_2O$. F. Mylius obtained the following results for the percentage solubility, *S* :

	0°	5°	10°	15°	10°	30°	60°	100°	100°
S .	13·92	17·84	26·21	32·79	25·29	33·36	43·67	60·84	c. 67
Solid phase	$H_2TeO_4.6H_2O$				$H_2TeO_4.2H_2O$				

The solubility expressed in mols. of H_2TeO_4 per 100 mols. of water is illustrated by Fig. 39. There is a transition temp. at 10° ; and the eutectic temp. is at —1·5°, although the hexahydrate is readily undercooled to —8°. L. Staudenmaier, and F. Mylius found that the crystals of the hexahydrate resemble those of potassium dihydrophosphate, and belong to the tetragonal system. They effloresce when dried between filter-paper, and pass into the orthotelluric acid by the heat of the hand. H. Remy discussed the structure of orthotelluric acid, H_6TeO_6.

The equilibrium conditions of orthotelluric acid, H_6TeO_6, or $H_2TeO_4.2H_2O$, are indicated in Fig. 42 ; and the acid is obtained by the spontaneous crystallization of aq. soln. The aq. soln. was prepared by J. J. Berzelius, H. L. Wells, and B. Brauner by dissolving tellurium in aqua regia. A. Mailfert obtained the acid by oxidizing tellurium with ozone in the presence of moisture ; A. Gutbier and F. Resenscheck, by oxidizing tellurium in alkaline soln. by hydrogen dioxide. A. Gutbier and W. Wagenknecht said that potassium tellurate is produced when a 15 per cent. soln. of hydrogen dioxide acts on a mixture of potassium hydroxide and tellurium dioxide at 60°–70°. When the soln. is acidified by sulphuric acid, telluric acid is precipitated and may be obtained free from potassium salts. Sodium hydroxide soln. may be substituted for potassium hydroxide. F. Becker oxidized tellurium dioxide with lead dioxide in nitric acid soln. The lead is afterwards removed by sulphuric acid, but, added L. Staudenmaier, it is difficult to free the telluric

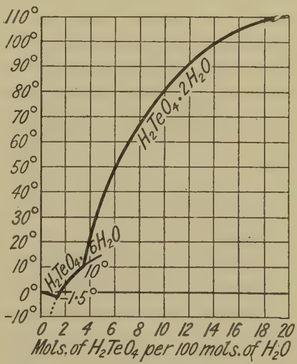

FIG. 42.—The Solubility of Telluric Acid in Water.

acid from lead and sulphuric acid. J. J. Berzelius oxidized tellurium dioxide to the trioxide by fusion with alkali nitrates; A. Oppenheim, by fusion with potassium chlorate; J. J. Berzelius, and P. E. Browning and H. D. Minnig, by the action of chlorine; L. Staudenmaier, by the action of bromine on silver tellurite: $Ag_2TeO_3+Br_2+H_2O=H_2TeO_4+2AgBr$; B. Brauner, by the action of iodine in alkaline soln.; B. Brauner, by the action of chromic acid in hydrochloric or sulphuric acid soln.; L. Staudenmaier, by the action of chromic acid in nitric acid soln.

The soln. of the element in aqua regia is freed from nitric acid by evaporation with an excess of hydrochloric acid. The soln. is diluted, filtered, and the tellurium precipitated by sodium bisulphite, and well washed with hot water. The moist tellurium is oxidized with nitric acid, and the resulting basic nitrate purified by recrystallization The basic nitrate is covered with several times its bulk of dil. nitric acid, and chromic anhydride slightly in excess of that required by the equation: $3TeO_2+2CrO_3+3H_2O=3H_2TeO_4+Cr_2O_3$ is added. The liquid is boiled and then evaporated until a crust forms on the surface. The crystals are removed from the cold soln. and the latter again evaporated. The operation is continued as long as telluric acid separates from the mother liquid. The acid is dissolved in hot water—if a white residue remains undissolved chromic anhydride insufficient to oxidize the tellurium dioxide is used. The acid must now be recrystallized a number of times in order to remove the chromium nitrate. The yield is about 80 per cent.

A. Gutbier and F. Flury found that when telluric acid is prepared by oxidizing a nitric acid soln. of tellurium dioxide with chromic acid, dark purple crystals of hydrated chromic nitrate, $Cr(NO_3)_3.9H_2O$, separate if too much chromic acid is used and they contain a very small quantity of telluric acid or tellurium nitrate. To obtain pure telluric acid, it is necessary to avoid excess of chromic acid; the telluric acid so obtained is quite colourless. Telluric acid should not be separated from a soln. containing sulphuric acid, for the solid substance retains this acid with great tenacity. J. Meyer and H. Moldenhauer obtained orthotelluric acid as a crystalline, snow-white powder, readily soluble in water, by oxidizing tellurium tetrachloride with chloric acid in the following manner:

Tellurium (10 grms.) is boiled with 10 c.c. of nitric acid and 3 c.c. of hydrochloric acid until completely dissolved. To the hot soln. is added gradually a conc. soln. of 9 grms. of chloric acid and the soln. is boiled until no more chlorine is evolved. A slight excess of chloric acid is added to avoid formation of any explosive chlorine oxide. The soln. is filtered through asbestos and concentrated by distillation in a vacuum on the water-bath, thereby removing chlorine. The telluric acid can be crystallized out by the addition of conc. nitric acid, collected, and finally freed from chlorine and nitrogen oxides by drying in vacuo.

J. Meyer and W. Franke modified this process. B. Brauner obtained telluric acid by the action of potassium permanganate in acidic or alkaline soln.; and K. B. Heberlein, by the anodic oxidation of a soln. of tellurium dioxide in nitric acid. P. E. Browning and H. D. Minnig tested if all the tellurous acid has been oxidized to telluric acid by making the soln. alkaline, and acidifying with acetic acid. If the soln. remains clear the oxidation to telluric acid is complete. S. Ghosh and N. R. Dhar, and W. von Behren and J. Traube studied the colloidal soln. of telluric acid.

The colourless **crystals** of orthotelluric acid were analyzed by L. Staudenmaier, and A. Gutbier. They occur in two forms—cubic and monoclinic. If a hot aq. soln. of orthotelluric acid be mixed with nitric acid a mixture of both forms of crystals is obtained. J. J. Berzelius described the crystals formed by the spontaneous evaporation of the aq. soln. as colourless, flattened, six-sided prisms with very obtuse summits, and often striated longitudinally; and if they separate from a soln. containing sulphuric acid, or from a warm, conc. soln., they are said to be short eight-sided prisms. W. Muthmann, and O. Brunck, and A. Gutbier thought these crystals were trigonal. The crystals were also studied by A. Oppenheim, L. Finckh, and A. Handl. B. Gossner obtained the monoclinic crystals by the slow evaporation of the aq. soln., or by cooling a warm, dil. nitric acid soln., and found the axial ratios to be $a:b:c=0·6104:1:0·5206$, and $\beta=104° 30'$. **Twinning,** and trilling occur about the (110)-plane; and fourlings were also observed. The

(010)-**cleavage** is clear. The **optical character** is positive; and the **optic axial angle** $2V=47° 30'$. The cubic crystals were observed by J. W. Retgers, and L. Staudenmaier. B. Gossner obtained the cubic forms in small singly refracting octahedra from a soln. of telluric acid in hot nitric acid of sp. gr. 1·32. They are accompanied by some monoclinic crystals—but the proportion of these decreases with the increasing conc. until finally only the cubic form appears. L. M. Kirkpatrick and L. Pauling found that the **X-radiogram** of the octahedral crystals corresponds with a face-centred, cubic lattice, with edge 15·48 A. A transformation of monoclinic to cubic crystals was not observed at temp. up to 130°; but the reverse transformation has been reported. P. Niggli discussed the **electronic structure** of the tellurates.

F. W. Clark gave for the **specific gravity** of ordinary orthotelluric acid, 3·00 at 25·5°; 2·965 at 26·5°. B. Gossner gave for the monoclinic crystals 3·071, and for the cubic crystals 3·053. Observations on the f.p. and b.p. of aq. soln. of telluric acid agree with measurements of the electrical conductivity. Irregularities in the b.p. measurements indicate the formation of some colloidal telluric acid. The abnormally large values for the temp. coeff. of the conductivity show that the complexity of the solute changes with rise of temp., so that the more complex modification which forms at the higher temp. is more strongly ionized. *Allo*telluric acid represents such a modification with a high conductivity. The fall in the conductivity of soln. of telluric acid at 25° continues until the value is characteristic of the crystallized acid. The depolymerization is also shown by the turbidity indicating the formation of a colloidal, insoluble modification. *Allo*telluric acid is therefore supposed to be not homogeneous, but rather a mixture of polymerized forms differing in complexity. J. O. Perrine observed no ultra-violet fluorescence when telluric acid crystals are exposed to X-rays for 5 hrs. S. Ghosh and N. R. Dhar studied the **viscosity** of colloidal soln. of telluric acid.

According to J. J. Berzelius, the **action of heat** on orthotelluric acid is such that it loses no water at 100°; and, according to L. Staudenmaier, none at 90°; but P. Köthner said that the acid loses some water when it is dried on the water-bath at 100°. J. J. Berzelius said that 2 mols. of water are lost at 160°, and L. Staudenmaier, 2 mols. at 140°. A. Gutbier found that when the acid is heated for half an hour at 110°–115°, it loses 8·00 per cent. of water—one mol is eq. to 7·84 per cent.; and in 2 hrs. at this temp. 9·14 per cent. of water is lost; when heated at 145°, until its weight is constant, the acid loses 13·20 per cent.; 17·01 per cent. at 170°; and when heated over the bunsen flame, 30·50 per cent. is lost. This corresponds with the transformation of orthotelluric acid to tellurium dioxide. A. Gutbier found that the **lowering of the freezing point** of water by the soln. of 0·3242 grm. of telluric acid in 20·1388 grms. of solvent is 0·140°, so that the mol. wt. of the acid is 218·5. The theoretical value for H_6TeO_6 is 229, and for H_2TeO_4, 193·6. From (i) the lowering of the f.p. of aq. soln.; (ii) the behaviour of the acid when heated; (iii) the ready passage of the hydrate $H_2TeO_4.6H_2O$ or $H_6TeO_6.3H_2O$ into H_6TeO_6; and (iv) the fact that unlike acids of the type H_6TeO_4, telluric acid it is not esterifiable, A. Gutbier inferred that both mols. of water in the hydrate $H_2TeO_4.2H_2O$ are constitutional so that the formula is H_6TeO_6, or $Te(OH)_6$. The powdered acid was found by L. Staudenmaier, and P. Köthner to lose no water over phosphorus pentoxide in vacuo. W. G. Mixter gave for the **heat of formation** $(Te,3O)=83·6$ Cals. According to R. Metzner, the **heat of solution** of the ortho-acid is −3·35 Cals.; but the heats of soln. of the meta-acid, and of the anhydride could not be determined. A. Gutbier found the **heat of neutralization** per mol is 13·38 Cals. F. Urban and V. W. Meloche used the refractometer for measuring the concentration of soln. of telluric acid. H. Nisi studied the Raman effect with the tellurates.

A. Rosenheim and G. Jander found the mol. **electrical conductivity,** μ, of aq. soln. containing a mol of H_2TeO_4 in v litres of water at 25° to be:

v .	4	8	16	32	64	128	256	513	1024
μ .	0·1902	0·1984	0·2029	0·2119	0·2245	0·2611	0·3131	0·4460	0·6913

Measurements of the H-ion concentration of the normal acid gave $[H^{\cdot}]=4\times10^{-5}$ gram-ion per litre at 25°. Assuming that the acid ionizes in accord with $H_6TeO_6 = H^{\cdot}+H_5TeO_6'$, this gives $K=1{\cdot}6\times10^{-4}$ for the ionization constant. Hence, orthotelluric acid is a very weak acid approximating boric and hydrocyanic acids. This is in agreement with the low values for the mol. conductivity. A. Miolati and E. Mascetti also followed the conductivity of the acid while being treated with progressive additions of sodium hydroxide. Measurements were also made by A. Gutbier. E. Blanc obtained for the **ionization constants** $K_1=6\times10^{-7}$, and $K_2=4\times10^{-11}$. As J. J. Berzelius showed, telluric acid is a feeble acid for it reddens blue litmus very feebly ; and A. Gutbier said that its **acidity** is about the same order as that of hydrogen sulphide or cyanide. K. B. Heberlein, and A. Gutbier said that telluric acid is so weak an acid that it cannot be titrated in the ordinary way, but with phenolphthalein in the presence of glycerol, K. B. Heberlein said that it can be titrated with sodium or potassium hydroxide soln. D. D. Karve said that ordinary telluric acid is inactive towards ethyl diazoacetate, and the indicator dimethylaminoazobenzene, and hence possesses the formula of a true acid, $Te(OH)_6$; *allo*-telluric acid is also a true acid ; but the so-called metatelluric acid behaves like a pseudo-acid so that its constitution is $O{=}Te(OH)_2{=}O$. F. Jirsa studied the effect of telluric acid on the potential of the silver anode. A. Oppenheim said that the ortho-acid is **diamagnetic.**

Ortho-telluric acid, said J. J. Berzelius, has a metallic not an acid taste. A. Oppenheim found that the tellurates are reduced to tellurides when heated with hydrogen. Orthotelluric acid is soluble in hot and cold **water ;** and F. Mylius' observations on the solubility are indicated above, Fig. 42. If the aq. soln. be evaporated on a water-bath to a syrupy consistency, the soln. crystallizes on cooling ; but if it be evaporated to dryness, an opaque, non-crystalline or glassy mass is produced which J. J. Berzelius found to dissolve in water very slowly. A. Gutbier made a similar observation ; and F. Mylius found that the slow-dissolving telluric acid is produced when orthotelluric acid is treated with conc. sulphuric acid at 60° to 90°. F. Mylius observed that the soln. have a great tendency to supersaturation during cooling. A. Gutbier and F. Flury observed that when aq. soln. of telluric acid are evaporated, a turbidity may be produced, but the suspension is so fine that it easily passes through a filter. The telluric acid may, however, separate as a gelatinous, voluminous mass. This substance has been dried in a desiccator and by heating at various temp., but no proof could be found of the existence of the telluric acid H_2TeO_4. The results obtained indicate that, besides telluric acid, H_6TeO_6, and its known, easily-soluble hydrate, there exist other difficultly-soluble hydrates, which all, however, lose water easily when heated, and give tellurium dioxide as the final residue. P. Köthner said that telluric acid volatilizes with steam when boiled with water ; but A. Gutbier denied this. The sat. aq. soln. was found by L. Staudenmaier to give a precipitate of the ortho-acid when treated with nitric acid ; and J. J. Berzelius obtained a similar result by the addition of alcohol. J. J. Berzelius found that telluric acid dissolved in cold, conc. **hydrochloric acid** can be evaporated at ordinary temp. without changing the telluric acid, but at 40°–45°, chlorine is evolved and the telluric acid is reduced to tellurium dioxide. F. A. Gooch and J. Howland found that telluric acid, in dil. sulphuric acid soln., is reduced to tellurium dioxide and tellurium by **hydriodic acid,** and to tellurium by **hydrobromic acid** in boiling soln. E. B. Benger found that with **sulphur,** in a sealed tube at 110°, a 30 per cent. aq. soln. of telluric acid is incompletely reduced ; with **selenium,** under similar conditions, tellurous and selenious acids are formed ; and with **tellurium,** tellurous acid is produced. The reducing action of **hydrogen sulphide** has been previously discussed ; the reaction was studied by A. Oppenheim, F. Becker, B. Brauner, L. Staudenmaier, A. Gutbier and co-workers, and E. B. Benger—*vide infra,* tellurium sulphides. B. Brauner found that **sulphur dioxide** in a sealed tube with an aq. soln. of telluric acid reduces it only partially to tellurium. E. B. Benger obtained confirmatory results. O. Brunck found that telluric acid or tellurates are reduced to tellurium by **sodium hyposulphite.** A. Gutbier and F. Flury found that a mixture of telluric acid or its salts with **ammonium chloride** behaves, when heated, like the mixture with ammonium chloride and tellurium dioxide (*q.v.*). P. Jannasch and M. Müller found that **hydrazine sulphate** precipitates tellurium in hydrochloric acid soln., but not so with nitric acid soln. The precipitation is quantitative when ammoniacal soln. are treated with hydrazine or **hydroxylamine.** A. Gutbier found that hydrazine hydrate, or **phenylhydrazine** assisted by heat reduces telluric acid quantitatively to tellurium; likewise also **hypophosphorous acid.** R. F. Weinland and H. Prause also found that the tellurates form complex salts with **phosphates** and **arsenates**—*vide infra.* J. J. Berzelius said that tellurates are reduced with feeble detonation when heated with **carbon,** and tellurides are formed. J. J. Berzelius found that when a tellurate is heated to redness with **potassium,** potassium telluride is formed, but not so with silver and zinc tellurates. Although telluric acid is so feeble an acid, E. B. Hutchins found that a hot conc. soln. will attack **arsenic, antimony** and **bismuth,** as well as many other metals—*e.g.* **silver, zinc, cadmium, mercury, aluminium, tin, lead,** and **nickel.** F. W. Clarke said that **thallium** is not attacked by a boiling soln. of telluric acid. F. Hundeshagen found that soluble gold chloride is produced by the action of **gold** on a hydrochloric acid soln. of telluric acid.

According to J. J. Berzelius, **metatelluric acid,** H_2TeO_4, is formed by heating the higher hydrate to 160° when the crystals are converted without change of form into an opaque mass which is yellow when hot, and white when cold. L. Staudenmaier found that the dehydration begins at 140°, and is at first rapid, then so slow that a week is not sufficient for the dehydration. At a higher temp., some telluric acid is decomposed. A. Gutbier could not prepare metatelluric acid; he assumed that it does not exist; the colourless telluric acid of J. J. Berzelius, and the yellow telluric acid of B. Brauner are said to be mixtures of tellurium trioxide and orthotelluric acid. K. B. Heberlein stated that if ordinary crystalline telluric acid be heated in a current of water vapour to 200°–210°, the product is 99 per cent. H_2TeO_4. According to F. W. Clarke, the sp. gr. of the white, flocculent metatelluric acid is 3·42 at 18·8°, 3·46 at 19·1°, and 3·44 at 19·2°. J. J. Berzelius, and L. Staudenmaier said that if the meta-acid be heated below redness, it gives off water forming tellurium trioxide; and at a red-heat, it is resolved into water, oxygen, and tellurium dioxide. L. Staudenmaier said that when heated in a current of hydrogen, it is reduced to tellurium, slowly at 300°, rapidly at a red-heat. J. J. Berzelius found that the meta-acid is very slowly but completely soluble in cold water, and is quickly dissolved by hot water.

TABLE I.—REACTIONS OF ALLOTELLURIC AND ORTHOTELLURIC ACIDS.

Reagents, etc.	Orthotelluric acid.	Allotelluric acid.
Taste	Sweet, metallic	Acidic
Alcohol	White pp. H_6TeO_6	No pp.
Congo red	Red	Blue
N-NaOH	No pp.	White pp. soluble in excess
Sod. carb.	No pp.	White pp. not soluble in excess.
Sod. silicate . . .	No pp.	White pp.
N-KOH	Soluble pp.	Sparingly soluble pp.
Pot. carb.	Soluble pp.	Sparingly soluble pp.
Aq. ammonia . . .	Soluble pp.	Sparingly soluble pp.
Guanidine carbonate . .	No pp.	White pp.
Albumin	No pp.	White pp.
Sodium thiosulphate . .	No pp. at first.	Separation of sulphur; brown pp.

F. Mylius found that when orthotelluric acid, H_6TeO_6, is heated to 140° it is converted into what he called **allotelluric acid**; and this is thought to be **trimeta-**

telluric acid, $(H_2TeO_4)_3$. It fuses at ordinary temp. giving a sticky, colourless mass which is miscible with water in all proportions. In the course of some months' contact with water, it furnishes crystals of orthotelluric acid. A comparison of the behaviour of allotelluric and orthotelluric acids towards some reagents is indicated in Table I. The albumin reaction with allotelluric acid is sensitive to one part of the acid in 5,000 parts of water. Cryoscopic determinations of aq. soln. show that the mol. wt. corresponds with $(H_2TeO_4)_{2\cdot 9}$. The action of water is slowly to resolve the complex into simpler mols. as in the analogous case of the polymetaphosphoric acids. The conductivity of allotelluric acid is five times as great as that of orthotelluric acid and allotelluric acid is, therefore, much the stronger acid. The electrical conductivity of a soln. of 0·089 grm. $(H_2TeO_4)_n$ per c.c. of water, initially K=0·0040, falls rapidly to 0·000071 in the course of a few days. D. Karve said that the absorption spectra agree with the assumption that ordinary telluric acid is $Te(OH)_6$; that metatelluric is a pseudo-acid of the constitution $(HO)_2TeO_2$; and allotelluric acid is a true acid, H_2TeO_4.

According to R. Metzner, if a soln. of tellurium dioxide in orthotelluric acid be slowly evaporated large prisms of orthotelluric acid, and small opaque, white spheres composed of small acicular crystals, of the composition *tellurosic oxide*, $2TeO_2.TeO_3$, or *tellurium tritaheptoxide*, Te_3O_7, or *telluryl tellurite*, $TeO(TeO_3)_2$, are formed. V. Lenher and E. Wolesensky also observed that in the oxidation of potassium pyrotellurite, the potassium tellurosate, $K_2O.TeO_3.TeO_2$, is formed as an intermediate compound.

§ 11. The Tellurates

What are called the normal tellurates appear as salts of *metatelluric acid*, H_2TeO_4, whilst salts of the *orthotelluric acid*, H_6TeO_6, appear as orthotellurates—*e.g.* Cu_3TeO_6, Ag_6TeO_6, Zn_3TeO_6, and Hg_3TeO_6. There are also salts of the hypothetical *pyrotelluric acid,* $H_2Te_2O_7$; and of the hypothetical *tetratelluric acid,* $H_2Te_4O_{13}$. The normal tellurates, $K_2TeO_4.2H_2O$, $Ag_2TeO_6.2H_2O$, etc., may really be orthotellurates, $K_2H_4TeO_6$ and $Ag_2H_4TeO_6$, respectively.

J. J. Berzelius[1] prepared normal **ammonium tellurate,** $(NH_4)_2.TeO_4$, by the action of solid aq. ammonia on powdered telluric acid; the white glutinous magma dissolves on boiling the mixture, and on cooling the clear soln. becomes turbid, but clarifies as white flakes and granules of this salt are deposited. That which remains in soln. may be precipitated by adding ammonium chloride, and afterwards alcohol. The precipitate is washed with alcohol, which exerts a slight solvent (peptizing) action as the ammonium chloride is washed away. The salt is also obtained by cooling a boiling ammoniacal soln. of normal potassium tellurate in ammonium chloride. F. W. Clarke gave 3·024 for the sp. gr. of the salt at 24·5°, and 3·012, at 25°. J. J. Berzelius said that the white powder dissolves completely in water—slowly if cold, rapidly if boiling. According to A. Gutbier, a boiling aq. soln. of ammonium tellurate—obtained by the action of aq. ammonia on orthotelluric acid—gives a white precipitate with sodium chloride but not with potassium chloride. J. J. Berzelius obtained **ammonium hydrotellurate,** $(NH_4)HTeO_4$, by adding ammonium chloride to a sat. soln. of the corresponding sodium salt. No precipitate is obtained if the potassium salt is employed. The precipitate adheres to the glass as a glutinous mass which dissolves with difficulty in water; and when boiled with water in open vessels, ammonia is evolved. If heated with water in a closed vessel, it partly melts to a white mass which solidifies on cooling, and part dissolves in the water but separates out on cooling. J. J. Berzelius also reported **ammonium hydropyrotellurate,** $(NH_4)HTe_2O_7$, to be formed by adding ammonium chloride to the corresponding sodium salt. The addition of alcohol facilitates the precipitation of the salt which is then washed with alcohol. If a soln. of the hydrotellurate is left to evaporate spontaneously, or by the aid of a gentle heat, the hydropyrotellurate remains as a gummy film. The salt fuses with intumescence when heated, and water is given off. The salt is slightly soluble in water. The colloidal nature of the ammonium tellurates was discussed by A. Rosenheim and G. Jander—*vide infra,* lithium tellurates. C. Ewald made a number of complex organic tellurates.

J. J. Berzelius prepared normal **lithium tellurate,** $Li_2TeO_4.nH_2O$, as a gum-like mass on evaporating the aq. soln. of telluric acid mixed with the required proportion of lithium hydroxide. F. Mylius obtained what was probably **lithium orthotellurate,** $Li_4H_2TeO_6.7H_2O$ by sat. a conc. soln. of orthotelluric acid with lithium hydroxide. The sparingly-soluble salt is hydrolyzed by water. J. J. Berzelius prepared **lithium hydrotellurate,** $LiHTeO_4.nH_2O$, as a gummy mass by evaporating a mixture of telluric acid and lithium hydroxide. A soln. of 4 mols of orthotelluric acid, and a mol of lithium carbonate in water, when spontaneously evaporated yields **lithium hydropyrotellurate,** $LiHTe_2O_7.nH_2O$, which, when heated to 100° forms insoluble **lithium tetratellurate,** $Li_2Te_4O_{13}$. A. Rosenheim and G. Jander showed that the lithium salts behave in many ways like the free acid—(i) they have no definite solubility in water; (ii) the quantity of water which the crystals contain varies according to the conc. of the liquid from which they are deposited; and (iii) they undergo dehydration without any appreciable change in their appearance. In these and other respects the salts resemble colloids—(i) they not only adsorb water, but (ii) the lithium salts and basic salts behave like adsorption compounds of telluric acid and lithium hydroxide.

J. J. Berzelius fused tellurium dioxide with sodium nitrate and obtained a sodium tellurate—*vide* potassium tellurate. According to F. Mylius, what appears to be **sodium dihydrorthotellurate,** $Na_4H_2TeO_6.7H_2O$, was obtained in slender, felted needles by supersaturating a conc. soln. of telluric acid with sodium hydroxide. It is hydrolyzed by water to **sodium tellurate,** $Na_2TeO_4.2H_2O$, which may be **sodium tetrahydrorthotellurate,** $Na_2H_4TeO_6$. This salt was prepared by J. J. Berzelius. He found that the *dihydrate* separates from a soln. of telluric acid in hot soda-lye partly on cooling and partly on the addition of alcohol. It is also obtained by evaporating to dryness, below 100°, a soln. of equimolar parts of telluric acid and sodium carbonate, so as to get rid of all the carbon dioxide, hence, sodium hydroxide is now used instead of the carbonate. The salt was also prepared and analyzed by A. Gutbier. The crystals of the salt do not part with all water until they are nearly at a red-heat. The salt is sparingly soluble in cold and hot water, and it does not separate on cooling the hot soln.; but if sodium hydroxide be added to the soln., the tellurate separates in grains. The evaporation of the aq. soln. on a water-bath leaves a soluble, soft, gummy mass which when dried is but sparingly soluble. F. Mylius said that the salt furnishes doubly refracting six-sided plates; and that at 18°, 100 parts of water dissolve about 0·77 part of salt, and at 100°, about 2·0 parts. R. Funk made some observations on the solubility of the salt. W. G. Mixter gave for the heat of formation $(Na_2O,TeO_3)=124·3$ Cals. A. Miolati and E. Mascetti found that the mol. electrical conductivity, μ, of a mol of Na_2TeO_4 is v litres, at 25°, is

v . .	32	64	128	256	512	1024
μ . .	90·65	94·83	98·33	100·5	103·9	107·6

F. Mylius said that the aq. soln. has an alkaline reaction, and is decomposed by carbon dioxide. E. Blanc calculated the percentage hydrolysis of a $0·0093N$-soln. to be 13·97. J. J. Berzelius added that the salt dehydrated below a red-heat remains white when hot, and dissolves in hot, dil. nitric acid, but in cold or hot water is peptized to a turbid liquid. According to F. Mylius, the *tetrahydrate*, $Na_2TeO_4.4H_2O$, is formed in prismatic crystals from a 30 per cent. soln. of telluric acid sat. with sodium hydroxide. It is more soluble than the dihydrate—100 parts of water dissolve about 1·43 parts of salt at 18°, and at 50°, about 2·5 parts. The salt in contact with water passes into the dihydrate in a few weeks at ordinary temp., and in a few hrs. at 60°. The tetrahydrate recalls the corresponding hydrate of sodium chromate; the *decahydrate* could not be prepared by F. Mylius, or R. Funk. A. Rosenheim and G. Jander made similar observations with respect to the colloidal nature of the sodium tellurates as of the lithium tellurates—*vide supra.*

According to J. J. Berzelius, **sodium hydrotellurate,** $NaHTeO_4.1\frac{1}{2}H_2O$, is obtained by dissolving telluric acid in a boiling soln. of sodium carbonate and adding acetic acid after cooling. The salt first precipitated is redissolved, and when the soln. is evaporated to dryness leaves a mixture of acetate and hydrotellurate—the acetate can be extracted with alcohol. The hydrotellurate is slowly but completely soluble in water, and when the soln. is spontaneously evaporated, it forms a gummy mass, which becomes milk-white when heated, and the product dissolves very slowly in water. When dehydrated by heat the hydrotellurate furnishes a mixture of soluble pyrotellurate and very sparingly soluble tellurate. The hydrotellurate is also produced from a soln. of 2 mols of telluric acid, and a mol of sodium carbonate. E. Blanc found that 0·117 per cent. of the salt is hydrolyzed in a $0·0093N$-soln. A soln. of four mols of orthotelluric acid, and a mol of sodium carbonate furnishes a gummy mass of **sodium hydropyrotellurate,** $NaHTe_2O_7$, when spontaneously evaporated. When heated, it furnishes insoluble **sodium tetratellurate,** $Na_2Te_4O_{13}$.

C. F. Rammelsberg, J. W. Retgers, L. Staudenmaier, and A. Gutbier could not prepare the crystallized, anhydrous **potassium tellurate,** K_2TeO_4, of A. Handl and V. von Lang, isomorphous with potassium sulphate; potassium tellurate shows no inclination to form isomorphous mixtures with potassium sulphate or selenate. J. J. Berzelius obtained the *pentahydrate*, $K_2TeO_4.5H_2O$, from a soln. of telluric acid and potassium hydroxide. The soft, glutinous mass dissolves on the application of a moderate heat, and on cooling the soln. to 0°, the pentahydrate crystallizes out completely provided the alkali-lye is not too dil. The crystals are washed with alcohol. If the alkali-lye is too dilute, the salt does not separate until alcohol is added. If the alcohol is added in small portions at a time, the salt separates in oily drops which afterwards crystallize; if a large quantity of alcohol is added at once, crystals of the salt separate out immediately. The salt was also obtained by J. J. Berzelius by evaporating to dryness a soln. of equimolar parts of telluric acid and potassium carbonate; but E. B. Hutchins added that the process gives a poor result because the telluric acid does not drive out the carbon dioxide from an eq. amount of potassium carbonate. The salt was obtained by the double decomposition of silver tellurate and potassium bromide dissolved in a little warm water, and slowly evaporating the liquid in air free from carbon dioxide. The analyses of A. Gutbier, L. Staudenmaier, J. J. Berzelius, and E. B. Hutchins agree with the formula $K_2TeO_4.5H_2O$; and this salt was found to be produced at ordinary temp. from neutral or slightly alkaline soln. According to J. W. Retgers, with conc. soln. of potassium hydroxide, doubly refracting crystals of the *dihydrate*, $K_2TeO_4.2H_2O$, are produced; and A. Gutbier, and E. B. Hutchins obtained crystals of the dihydrate from a soln. of orthotelluric acid in a boiling, conc. soln. of potassium hydroxide. According to J. J. Berzelius, the pentahydrate furnishes prismatic crystals which, according to L. Staudenmaier, belong to the monoclinic system. J. J. Berzelius found that the pentahydrate when heated gives off water and sinters to a white mass; and A. Gutbier added that at 200°, water and oxygen are given off, and tellurite is formed. According to J. J. Berzelius, when the crystals of the pentahydrate are exposed to air, they become moist without deliquescence forming a mixture of hydrotellurate and carbonate. The salt is soluble in water but not in alcohol. A small proportion of one of the stronger acids added to the aq. soln. precipitates the hydrotellurate; a larger proportion of acid precipitates the pyrotellurate; while a still larger proportion of acid removes all the alkali forming a clear soln. If the acid be acetic acid, the evaporation of the clear soln. furnishes a mixture of potassium acetate and tellurate. A. Rosenheim and G. Jander made similar observations with respect to the colloidal nature of the potassium tellurates as were made in the case of the lithium tellurates—*vide supra.* C. Hugot found that potassium tellurate suspended in dil. hydrochloric acid, and treated with zinc, or suspended in dil. alkali-lye, and treated with aluminium, furnishes tellurium.

According to J. J. Berzelius, **potassium hydrotellurate,** $KHTeO_4.1\frac{1}{2}H_2O$, is formed from a soln. of the correct proportion of potassium carbonate in orthotelluric acid evaporated at ordinary temp.; by cooling a boiling soln. of 2 mols of orthotelluric acid and a mol of potassium carbonate; while the exposure of a soln. of the normal tellurate to air results in the deposition of the hydrotellurate, and, added E. B. Hutchins, this salt is precipitated on passing carbon dioxide into an aq. soln. of the normal salt—an excess of the carbon dioxide does no harm. J. J. Berzelius also obtained the hydrotellurate by evaporating to dryness a soln. of the normal tellurate in acetic acid, and washing out the acetate with alcohol of sp. gr. 0·85. He also obtained the salt by fusing tellurium dioxide with potassium nitrate to a clear liquid; digesting the cold mass with boiling water to remove nitrites and nitrates; and dissolving the residue in boiling water—it does not dissolve in water holding nitrate in soln. When the hot soln. is cooled, crystals of the hydrotellurate are deposited. The higher the fusion temp. the greater the proportion of tellurite mixed with the tellurate. This process, added J. J. Berzelius, sometimes yields a product which is insoluble in boiling water, acids, or soln. of alkalies; it is white when cold, yellow when hot, and when heated fuses giving off oxygen and forming potassium pyrotellurite. E. B. Hutchins' analysis of the hydrotellurate corresponds with $K_2O.2TeO_3.4H_2O$. The salt has an alkaline reaction, and it has a metallic, slightly alkaline taste. When heated, it gives off water, turns yellow, and at a higher temp.—below redness—fuses forming normal tellurate and tetratellurate: $6KHTeO_4=2K_2TeO_4+K_2Te_4O_{13}+3H_2O$—the tellurate can be extracted by water. The hydrotellurate is sparingly soluble in cold water, but more soluble in hot water.

J. J. Berzelius prepared **potassium hydropyrotellurate,** $KHTe_2O_7.1\frac{1}{2}H_2O$, by slowly cooling a boiling soln. of 4 mols of orthotelluric acid and a mol of potassium carbonate. E. B. Hutchins' analysis agree with $K_2O.4TeO_3.4H_2O$. J. J. Berzelius found that this salt is precipitated when nitric acid is added to an aq. soln. of the normal tellurate: and, as indicated above, it is formed by adding nitric acid to the aq. soln. obtained as above by fusing tellurium dioxide and potassium nitrate. The white, pulverulent salt loses 7·5 per cent. of water at a gentle heat, but retains 0·15 per cent.; it then turns yellow and forms the tetratellurate; and at a higher temp., it gives off 7·71 per cent. of oxygen leaving potassium tellurite behind. The salt is slightly soluble in water; when crystallized from its aq. soln., some hydrotellurate is formed; if the water contains other salts in soln., this decomposition does not occur. E. B. Hutchins prepared **potassium tritellurate,** $K_2Te_3O_{10}.5H_2O$, by evaporating a soln. of a mol of potassium carbonate, and 4 mols of telluric acid. It furnishes a white, granular mass which is much more soluble in hot than in cold water; the aq. soln. has an alkaline reaction. J. J. Berzelius prepared **potassium tetratellurate,** $K_2Te_4O_{13}$, by calcining the hydropyrotellurate; by very gently heating tellurium dioxide with potassium chlorate, and extracting the product with water to remove potassium chloride and chlorate; by the action of chlorine on a hot soln. of potassium tellurite, and washing the product with water; and also by heating orthotelluric acid with potassium nitrate and chloride below redness, and washing with water. The yellow powder is insoluble at ordinary temp. in water, dil. mineral acids, and potash-lye; it slowly dissolves in boiling nitric acid, and rapidly in molten potash-lye.

J. F. Norris and W. A. Kingman prepared **rubidium tellurate,** $Rb_2TeO_4.3H_2O$, by evaporating in vacuo over sulphuric acid, a soln. of orthotelluric acid mixed with a 25 per cent. excess of rubidium hydroxide. The colourless prisms with pyramidal ends dissolve in ten times their weight of water. The salt is decomposed by carbon dioxide so that it cannot be made from orthotelluric acid and rubidium carbonate. If a soln. of rubidium carbonate and telluric acid in calculated quantities be evaporated, **rubidium hydrotellurate,** $RbHTeO_4.\frac{1}{2}H_2O$, is formed. It is not isomorphous with the corresponding hydroselenate; 100 parts of cold water dissolve about 5 parts of the salt; the salt is more soluble in hot water. G. Pellini mixed nearly sat. aq. soln. of rubidium hydrotellurate and hydroselenate, in various proportions, and on evaporating the mixed soln. at 50°–80° until they deposited crystals on cooling, obtained mixed crystals of the two salts containing from 42 to 53 mols. per cent. of the selenate. With soln. still richer in selenate, crystals containing up to 100 per cent. selenate can be obtained. There is, however, a limit to the proportion of tellurate in the mixed crystals since all soln. containing more than about 50 molar per cent. of the tellurate deposit the latter in the pure state. With mixed soln. of rubidium hydrosulphate and hydrotellurate, the results can be interpreted on the assumption that a complex salt, $RbHSO_4.RbHTeO_4$, is formed; but there is also a tendency to form solid soln. J. F. Norris and W. A. Kingman prepared by an analogous process, **cæsium hydrotellurate,** $CsHTeO_4.\frac{1}{2}H_2O$, which is produced in small cubic crystals, less soluble than those of the rubidium salt—100 parts of water dissolve about 3·33 parts of the salt.

J. J. Berzelius described the green flocculent precipitate obtained by mixing soln. of potassium tellurate and copper nitrate as normal **copper tellurate,** $CuTeO_4$. E. B. Hutchins showed that if the precipitate be boiled for some hours with water, it forms **copper orthotellurate,** Cu_3TeO_6, which settles as a heavy green powder. It is insoluble in water but soluble in aq. ammonia, a soln. of potassium cyanide, and in acetic, hydrochloric, or nitric acid. No success attended the attempt to obtain the tellurate in a crystalline form by allowing the precipitate to remain in the mother-liquor for weeks; or by allowing copper hydroxide to stand for weeks in contact with an excess of telluric acid.

J. J. Berzelius obtained normal **silver tellurate,** Ag_2TeO_4, in dark yellow, bulky flakes on adding a conc. soln. of silver nitrate to one of normal potassium tellurate. E. B. Hutchins could not prepare the salt in this way, he always obtained a basic salt, and by using potassium hydrotellurate, he obtained a precipitate containing an excess of telluric acid; and, as observed by A. Gutbier, the product is decomposed into the basic salt by washing. E. B. Hutchins obtained crystals of the *dihydrate*, $Ag_2TeO_4.2H_2O$, which may be **silver tetrahydrorthotellurate,** $Ag_2H_4TeO_6$, by treating silver oxide with an excess of a soln. of telluric acid; by mixing a soln. of 20 grms. of silver acetate, acidified with a few drops of acetic acid, with a soln. of 1·4 grms. of telluric acid, and evaporating the soln. at room temp. in darkness; and by adding a silver nitrate soln. to a conc. soln. of potassium tellurate containing an excess of acetic acid, and allowing the yellow or brown precipitate to stand for some hours in contact with the mother-liquid. Owing to their greater sp. gr., the crystals can be easily separated from the amorphous salt. The straw-yellow crystals are rhombic bipyramids with the axial ratios $a : b : c = 0·722 : 1 : 2·107$, and they are isomorphous with the corresponding sulphate and selenate. The crystals are slowly darkened in light; and when heated to 200°, they lose water and become black; at a higher temp. oxygen is evolved and a greyish-brown, fusible mass remains. The salt is insoluble in hot or cold water, but soluble in aq. ammonia, an aq. soln. of potassium cyanide, or sodium thiosulphate, and in nitric, sulphuric, and acetic acids. Conc. acids decompose the salt completely forming telluric acid and the corresponding silver salt. J. J. Berzelius said that by mixing an ammoniacal soln. of silver tellurate with ammoniacal silver nitrate, and evaporating, the basic salt, **silver dioxytellurate,** $2Ag_2O.Ag_2TeO_4$, or possibly **silver orthotellurate,** Ag_6TeO_6, is formed; and the same product is obtained by treating a dil. soln. of silver nitrate with potassium tellurate. The reddish-yellow precipitate soon blackens. J. J. Berzelius also prepared **silver oxyditellurate,** $Ag_2O.2Ag_2TeO_4$, or $Ag_6Te_2O_9$, as a brown powder by boiling silver nitrate with water. E. B. Hutchins said that if the crystals of dihydrated silver tellurate are allowed to stand in contact with a cold soln. of a silver salt, red monoclinic crystals of the *trihydrate*, $Ag_6Te_2O_9.3H_2O$, are formed. They are not changed by cold water, but with boiling water a brown mass is formed. In sunlight the crystals become opaque and copper-red. If heated over 110°, the salt loses water and becomes black; all the combined water is expelled at 200°. J. J. Berzelius said that by double decomposition with silver nitrate and potassium hydrotellurate, **silver hydrotellurate,** $AgHTeO_4$, is formed; likewise also **silver tetratellurate,** $Ag_2Te_4O_{13}$; but E. B. Hutchins could obtain neither of these salts.

E. B. Hutchins did not succeed in making **gold tellurate.** If gold chloride be added to normal silver tellurate suspended in water, silver chloride and gold oxide are precipitated; and the evaporation over sulphuric acid of a mixed soln. of potassium tellurate and gold chloride furnishes yellow crystals of potassium chloroaurate.

J. J. Berzelius prepared **calcium tellurate,** $CaTeO_4$, by precipitation. The white flecks dissolve in hot water, and the evaporation of the soln. yields a white powder; **strontium tellurate** was obtained in an analogous manner; and **barium tellurate,** $BaTeO_4.3H_2O$, appears as a voluminous, white precipitate when a soln. of barium chloride is treated with sodium tellurate. The precipitate soon forms a heavy, white powder. It loses its water of crystallization when heated over 200°. F. C. Mathers and G. M. Bradbury found that when tellurium dioxide is mixed with 5 eq. of tellurium dioxide, and heated for an hour at 975°, almost the theoretical yield of calcium tellurate is formed. At a lower temp. the yield was smaller. F. W. Clarke gave 4·55 for the sp. gr. of anhydrous barium tellurate at 10·5°; 4·53 at 10°; and 4·48 at 16°; when dried at 200°, the sp. gr. is 4·2. J. J. Berzelius found that barium tellurate is sparingly soluble in cold water, and rather more soluble in hot water. When the aq. soln. is evaporated a white earth remains. It is not decomposed by ammonia; and it is soluble in hydrochloric and nitric acids. If sodium hydrotellurate be added to a soln. of barium chloride a voluminous precipitate of **barium hydrotellurate,** $Ba(HTeO_4)_2.2H_2O$, was obtained. It is resolved by water into a soluble acid salt, and into the normal tellurate. Sodium hydropyrotellurate precipitates **barium hydropyrotellurate,** $Ba(HTe_2O_7)_2.nH_2O$, from a soln. of barium chloride. The voluminous precipitate is easily soluble in water; and in acetic acid. It is yellow when hot, white when cold.

J. J. Berzelius obtained **beryllium tellurate** as a white, voluminous precipitate by double decomposition with a soluble tellurate and a beryllium salt; and **magnesium tellurate** in an analogous manner. Magnesium tellurate is more soluble than the corresponding salts of the alkaline earths. Sodium hydrotellurate precipitates from a soln. of a magnesium salt, **magnesium hydrotellurate,** which is more soluble than the normal tellurate. A. Gutbier prepared **zinc tellurate** as a white, insoluble precipitate by mixing soln. of potassium tellurate and zinc chloride. E. B. Hutchins showed that the precipitate obtained with soln. of zinc nitrate and potassium tellurate becomes heavy and granular when treated with hot water. Its composition is Zn_3TeO_6; it is insoluble in water, but soluble in acetic, nitric, hydrochloric, and sulphuric acids. A. Oppenheim obtained **cadmium tellurate** as an insoluble white precipitate on treating cadmium nitrate with sodium tellurate. It forms a colourless soln. with hydrochloric acid.

J. J. Berzelius noticed that when powdered crystalline mercurous nitrate is immersed in an aq. soln. of potassium hydrotellurate, a dark brown precipitate is formed; and a yellowish-brown precipitate of **mercurous tellurate,** Hg_2TeO_4, is produced by the action of potassium tellurate on a soln. of mercurous nitrate. G. Denigès also obtained this salt in a similar way. J. J. Berzelius said that mercurous tellurate soon becomes yellow, owing to the action of the free acid in the liquid probably forming mercurous hydrotellurate, $HgHTeO_4$. Crystals of the normal mercurous tellurate have not been prepared. F. A. Genth discovered radiating tufts of minute, acicular or capillary, white crystals as a decomposition product of coloradoite in a mine in the Magnolia district, Colorado; and he called the mineral **magnolite.** He inferred that its composition is mercurous tellurate, Hg_2TeO_4, since it behaves towards hydrochloric acid somewhat as represented by the equation: $Hg_2TeO_4+8HCl=2HgCl_2+TeCl_4+4H_2O$. It is blackened by aq. ammonia, and is soluble in dil. nitric acid. E. B. Hutchins found that when a large excess of a cold conc. soln. of potassium tellurate is added to a conc. soln. of mercurous nitrate the yellow precipitate, which is first formed, quickly changes to a brown. The precipitate is slimy and difficult to wash. It approximates Hg_2TeO_4 in composition. E. B. Hutchins was unable to prepare **mercurous orthotellurate,** Hg_6TeO_6. When the bulky yellow precipitate, obtained by treating a hot dil. soln. of potassium tellurate with an excess of mercurous nitrate soln., is washed with hot water and boiled for some time in water it is decomposed, giving free mercury. The precipitate may be boiled for several hours without changing in appearance, but at length it settles as a heavy, brown granular powder containing free mercury. This change may be hastened by rubbing some of the precipitate against the side of the beaker with a glass rod. When the brown powder is heated with hydrochloric acid, elementary tellurium is precipitated. A. Oppenheim obtained mercurous tellurate by the action of telluric acid on a soln. of mercurous nitrate. E. B. Hutchins showed that if an excess of mercurous nitrate is employed with a hot dil. soln. of potassium tellurate, a yellow, amorphous, basic salt, **mercurous oxyditellurate,** $Hg_2O.2HgTeO_4$, is formed. A basic salt was also prepared by F. Teltscher. E. B. Hutchins found that when conc. soln. of mercurous nitrate and a soluble tellurate or telluric acid are mixed, the precipitate may vary in composition from the basic salt just indicated to **mercurous hydrotellurate,** $HgHTeO_4$, any precipitate of mercurous tellurate may be changed to crystals of the hydrotellurate by treatment with a cold conc. soln. of telluric acid. This acid tellurate is not only the only crystalline mercurous tellurate that has been prepared, but it is the only mercurous tellurate of definite composition that has been obtained. Mercurous tellurate is a striking example of a salt of a weak acid and a weak base. Slight variations of the conditions under which a salt is placed may bring about a change in its composition, causing it to become either more acid or more basic. This, together with the fact that the salt is readily decomposed giving free mercury and mercuric tellurate, renders the preparation of the mercurous tellurates somewhat difficult. The *trihydrate*, $HgHTeO_4.3H_2O$, may be conveniently prepared by treating a soln. of mercurous nitrate with telluric acid and subsequent change of the precipitate to the crystalline salt. When the soln. of telluric acid is added to a soln. of mercurous nitrate a bright yellow precipitate is formed. If a large excess of telluric acid is added, the yellow precipitate becomes nearly white and slowly changes to colourless crystals of $HgTeO_4.3H_2O$. The presence of considerable free nitric acid in the soln. aids greatly in the formation of crystals of the salt. Under these conditions crystals frequently form on the walls of the containing vessel. F. Teltscher found that the potential of platinized platinum in water with mercurous tellurate, $Hg_2TeO_4.6HgO.6H_2O$, in suspension, is —1·025 volt in darkness, and —0·1000 volt in light; if $0{\cdot}25N$-H_2TeO_4 is used in place of water, the values are respectively —0·93 and —0·96 volt; and with N-H_2TeO_4, —0·93 and —0·94 volt.

J. J. Berzelius, F. Teltscher, and E. B. Hutchins prepared **mercuric tellurate,** $HgTeO_4$, as a white, flocculent precipitate by mixing conc. soln. of mercuric nitrate and potassium tellurate or telluric acid at 0°. E. B. Hutchins found that the precipitate is quickly decomposed by water at room temp. into telluric acid and basic mercuric tellurate. This decomposition goes on even when the precipitate is washed with water at 0°: consequently it is impossible to obtain a pure white product in suitable condition for analysis. The precipitate remains white indefinitely in a sat. soln. of telluric acid at room temp. Crystals of the *dihydrate*, $HgTeO_4.2H_2O$, free from the basic salt were obtained by mixing conc. soln. of telluric acid and mercuric nitrate at 0° and allowing the resulting soln. to stand at room temp. until the salt crystallized out. The dihydrate appears as transparent crystals belonging to the orthorhombic system. It is slowly decomposed by cold water. Boiling water quickly decomposes it into telluric acid and basic mercuric tellurate. If the white precipitate of mercuric tellurate formed by mixing conc. soln. of mercuric nitrate and potassium tellurate containing free nitric acid, is allowed to remain undisturbed in the mother-liquor for several days at room temp., nearly all of it is converted into crystalline **mercuric orthotellurate,** Hg_3TeO_6, corresponding with turpeth mineral, Hg_3SO_6. Indeed, all precipitates of mercuric tellurate, whether crystalline or amorphous, show a strong tendency to change to mercuric orthotellurate in the presence of water. This property of mercuric tellurate renders it difficult to prepare the salt $HgTeO_4$ in pure condition. When an excess of mercuric nitrate is added to a hot dil. soln. of potassium tellurate, a heavy, yellow granular precipitate of mercuric orthotellurate is formed. If a cold, conc. soln. of mercuric nitrate is added to a conc. soln. of potassium tellurate made acid with nitric acid, a white flocculent precipitate of $HgTeO_4$ is formed. At room temp. a portion of the precipitate usually assumes a yellow colour immediately, probably due to the formation of a basic salt. If the acid soln. containing this white or yellow flocculent precipitate is allowed to stand undisturbed for several days the precipitate is largely converted into transparent amber-coloured crystals of the orthotellurate. Frequently the walls of the containing vessel are covered with crystals that have separated from the acid soln. In many cases the amber-coloured crystals form in contact with the white amorphous precipitate, but in all cases the crystals are entirely distinct from the precipitate. Mercuric orthotellurate crystallizes in the cubic system, the predominating form being the dodecahedron. Combinations of the cube and dodecahedron are frequent, while many crystals show a broad octahedral face on which the crystal has grown. The crystals contain a little nitric acid and about 0·6 per cent. of water. This is considerably less than one-half of a mol of water to one of Hg_3TeO_6. When heated, the salt assumes a red colour, but it regains its original colour upon cooling. The crystals are not altered by heating to 140°. The crystals are insoluble in water and unchanged by boiling with water. They are soluble in nitric acid but more readily soluble in hydrochloric acid. W. von Behren and J. Traube studied the stability of the colloidal soln. of the tellurate, $Hg_3H_3TeO_6$. F. Teltscher stated that he had obtained a basic *mercuric tellurate*, $Hg_2O.6HgO.TeO_3.6H_2O$, by the action of a conc. soln. of mercurous nitrate on a soln. of telluric acid. The yellow precipitate can be kept a long time in darkness without change, but it blackens in daylight.

J. J. Berzelius prepared **aluminium tellurate** as a white precipitate by the action of a soluble tellurate on a soln. of an aluminium salt. The precipitate is soluble in an excess of the aluminium salt. A. Oppenheim was unable to prepare *potassium aluminium tellurate* analogous to the alums. F. W. Clarke prepared **thallous tellurate,** Tl_2TeO_4, by mixing soln. of ammonium tellurate and thallous nitrate. The heavy, white precipitate recalls that of silver chloride. L. M. Dennis and M. Doan also obtained it as a white flocculent precipitate, sparingly soluble in water, by mixing soln. of telluric acid and thallous hydroxide. F. W. Clarke found that when dried at 120°, its sp. gr. is 5·712 at 20°; and 5·687 at 22°. When heated to 180°, the salt becomes pale yellow with the loss of 1·46 per cent. of water, and its sp. gr. is then 6·742 at 16°, and 6·760 at 17·6°. It melts at a red-heat and is reduced to telluride. When hot the colour is black, but on cooling it forms a clear, lemon-yellow glass. J. J. Berzelius obtained **yttrium tellurate** by a method analogous to that used for the aluminium salt. A. Gutbier mixed aq. soln. of telluric acid or an alkali tellurate with an aq. soln. of ammonium cerium nitrate, and obtained a pale yellow, slimy precipitate of **cerous tellurate.** J. J. Berzelius prepared **zirconium tellurate** as a voluminous, white precipitate on mixing soln. of zirconium chloride and sodium hydrotellurate: the precipitate is soluble in an excess of the zirconium salt; likewise also with thorium tellurate which is insoluble in an excess of the thorium salt. A. Gutbier also obtained **thorium tellurate,** as a white, curdy precipitate, from a soln. of potassium tellurate and thorium nitrate.

I. Domeyko mentioned the occurrence of lead tellurate in a mine in the province of Coquimbo, Chile. J. J. Berzelius said that a basic salt is produced as a voluminous, white precipitate when potassium hydrotellurate and basic lead acetate soln. are mixed; he obtained **lead tellurate,** $PbTeO_4$, by mixing soln. of normal lead acetate and potassium tellurate; the white, heavy precipitate is sparingly soluble in water; by the use of alkali hydrotellurate, **lead hydrotellurate,** $Pb(HTeO_4)_2.nH_2O$, is formed, and it is more soluble in water than the normal tellurate. F. C. Mathers and F. V. Graham obtained lead tellurate by the action of lead dioxide on tellurium dioxide at 170°. According to J. J. Berzelius, a precipitate of **lead tetratellurate,** $PbTe_4O_{13}$, is produced when an alkali tetratellurate is used as precipitant. It is yellow when hot, and white when cold. It is soluble in dil. nitric acid, even after ignition; less soluble in acetic acid; and fairly soluble in water.

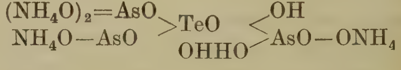
A. Oppenheim was unable to prepare an **arsenic tellurate.** According to R. F. Weinland and H. Prause, telluric acid unites with the arsenates of the alkali metals to form complex salts. Thus, **ammonium diarsenatotellurate,** $2(NH_4)_2O.As_2O_5.TeO_3.4H_2O$, was obtained by adding 4 mols of aq. ammonia to a soln. of orthotelluric acid and 4 mols of ammonium dihydroarsenate, in as little water as possible, at ordinary temp., and evaporating the soln. over sulphuric acid. The triclinic crystals are isomorphous with the corresponding phosphate, and have the axial ratios $a:b:c=0·7241:1:0·7468$, and $\alpha=90° 34'$, $\beta=94° 7'$, and $\gamma=92° 17'$. Likewise **ammonium triarsenatotellurate,** $4(NH_4)_2O.3As_2O_5.2TeO_3.11H_2O$, was obtained using a mol of orthotelluric acid, 4 mols of ammonium dihydroarsenate, and a mol of ammonia. The crystals are isomorphous with the corresponding phosphate. Similarly, using a mol of orthotelluric acid, 4 mols of arsenic acid, and 5·2 mols of sodium hydroxide, **sodium arsenatotellurate,** $2Na_2O.As_2O_2.2TeO_3.9H_2O$, was obtained in small, six-sided plates. *Potassium and rubidium arsenatotellurates* could not be prepared. The graphic formulæ given for the above salts are:

$$\begin{matrix}(NaO)_2{=}AsO \\ HO{-}TeO_2\end{matrix}\!>\!O$$

$2Na_2O.As_2O_5.2TeO_3.9H_2O$

$$\begin{matrix}(NH_4O)_2{=}AsO \\ (NH_4O)_2{=}AsO\end{matrix}\!>\!TeO_2$$

$2(NH_4)_2O.As_2O_5.TeO_3.4H_2O$



$$\begin{matrix}(NH_4O)_2{=}AsO \\ NH_4O{-}AsO\end{matrix}\!>\!\begin{matrix}TeO \\ OHHO\end{matrix}\!<\!\begin{matrix}OH \\ AsO{-}ONH_4\end{matrix}$$

$4(NH_4)_2O.3As_2O_5$

A. Oppenheim could not prepare *antimony tellurate.* F. A. Genth found a yellowish-, greenish- or brownish-red, soft, earthy incrustation, without distinct crystalline structure on the tetradymite of Highland, Montana, and he called the mineral **montanite ;** it was also found by T. W. E. David to accompany the tetradymite of Norongo, New South Wales. Analyses reported by F. A. Genth, T. W. E. David, and C. F. Rammelsberg, agree with $Bi_2O_3.TeO_3.2H_2O$, or $Bi_2O_3.TeO_3.H_2O$. It can therefore be regarded as a hydrated **bismuth orthotellurate,** $Bi_2TeO_6.2H_2O$, hydrated **bismuthyl tellurate,** $(BiO)_2TeO_4.H_2O$, or, according to P. Groth and K. Mieleitner, $\{Bi(OH)_2\}_2TeO_4$.

J. J. Berzelius prepared **chromic tellurate** in greyish-green flecks by mixing soln. of a chromic salt and an alkali tellurate. It is soluble in an excess of a chromic salt soln., but not in soln. of potassium tellurate or sulphate. A. Oppenheim also prepared this salt, but he was unable to obtain *potassium chromium tellurate* analogous to chrome-alum. A. Berg evaporated spontaneously an aq. soln. containing 2 mols of chromium trioxide and a mol each of potassium dichromate and telluric acid. An ill-defined crystalline crust of **potassium chromotellurate,** $2K_2O.4CrO_3.TeO_3$, was obtained ; similarly with **ammonium chromotellurate,** $2(NH_4)_2O.4CrO_3.TeO_3$; and the very soluble **sodium chromotellurate,** $2Na_2O.4CrO_3.TeO_3$. He regarded these salts as derivatives of **chromotelluric acid,** $TeO(O.CrO_2.OH)_4$, which, in turn, is derived from *paratelluric acid,* $TeO(HO)_4$.

V. W. Meloche and W. Woodstock obtained **ammonium telluratohexamolybdate,** $3(NH_4)_2O.TeO_3.6MoO_3.7H_2O$, from a soln. of a mol of telluric acid and 4 mols of molybdic acid with enough aq. ammonia to satisfy the telluric acid, by evaporation and crystallization. A soln. of equimolar proportions of telluric and molybdic acids, with enough ammonia to satisfy half the hydrogen atoms of telluric acid, H_2TeO_6, on evaporation and cooling, gave clear, white crystals of **ammonium ditelluratohexamolybdate,** $3(NH_4)_2O.2TeO_3.6MoO_3.10H_2O$. Both compounds decompose at 550° leaving a residue of tellurium dioxide with a small amount of molybdic acid.

J. J. Berzelius similarly prepared **uranyl tellurate** as a voluminous pale yellow precipitate insoluble in an excess of uranyl nitrate soln. A. Gutbier found it to be readily soluble in cold hydrochloric acid. J. O. Perrine said that it shows no ultra-violet fluorescence with the X-rays.

J. J. Berzelius obtained **manganese tellurate** as a white flocculent precipitate by mixing soln. of alkali tellurate and a manganese salt. J. J. Berzelius obtained **ferric tellurate** in pale yellow flakes soluble in an excess of the ferric salt ; and **ferrous tellurate** as a white precipitate, which, on exposure to air, becomes greenish-grey and then brownish-red. F. A. Genth reported a straw-yellow to greenish-yellow mineral which he called **ferrotellurite** occurring at the Keystone Mine, Magnolia District, Colorado. It was supposed to be ferrous tellurate, $FeTeO_4$, but, according to J. D. Dana, the crystals may have been those of tellurite coloured with ferric oxide. The mineral was insoluble in aq. ammonia ; and soluble in hydrochloric acid. J. J. Berzelius obtained **cobalt tellurate,** as a voluminous bluish-purple precipitate, and **nickel tellurate** as a pale green precipitate.

J. F. Norris and H. Fay could not prepare any **tellurothionates** analogous to selenotetrathionate.

§ 12. Tellurium Halides

H. Moissan[1] found that powdered tellurium put in contact with fluorine combines with incandescence giving an abundance of white fumes. The whole mass is quickly covered with a solid, crystalline fluoride, easily volatile and very hygroscopic, having the aspect and properties of the **tellurium tetrafluoride,** TeF_4, described by J. J. Berzelius; but E. B. R. Prideaux showed that the product is the hexafluoride—*vide infra*. J. J. Berzelius prepared the tetrafluoride by dissolving tellurium dioxide in hydrofluoric acid, evaporating the liquid on a water-bath to a transparent, colourless syrup which, on cooling, solidified to a milk-white mass of small, warty granules. When the product is heated, water and hydrofluoric acid are given off, and finally a sublimate of tellurium tetrafluoride—an oxyfluoride remains as a residue. R. Metzner treated the mother-liquor, used in the preparation of the oxyfluoride, $TeOF_2.H_2O$, with liquid hydrogen fluoride, cooled to —70°; on raising the temp. to —28°, the liquid portion is removed, and there remain crystals of the tetrafluoride which can be dried on paper at —30°. E. B. R. Prideaux and J. O'Neil Millott did not observe this separation of the tetrafluoride. A *tetrahydrate*, $TeF_4.4H_2O$, was prepared by A. J. Högbom.

A number of **fluotellurites** has been prepared from soln. of tellurous acid and various hydroxides and carbonates in hydrofluoric acid. Thus, H. L. Wells and J. M. Willis prepared **cæsium pentafluotellurite,** $CsTeF_5$, from mixed soln. of tellurium dioxide and cæsium fluoride in hydrofluoric acid. The salt forms transparent, colourless needles. It is decomposed by water; but it is stable in hydrofluoric acid soln. A. J. Högbom prepared **ammonium pentafluotellurite,** $NH_4TeF_5.H_2O$, which furnishes colourless prismatic crystals; **potassium pentafluotellurite,** $KTeF_5$, gives long colourless needles; and **barium pentafluotellurite,** $Ba(TeF_5)_2.H_2O$, gives irregular lamellæ. The crystals become opaque when exposed to air; and are decomposed by water. The fluotellurites of copper, silver, beryllium, and nickel could not be prepared. J. J. Berzelius described **sodium fluotellurite** as a compound which formed ill-defined crystals soluble in a small proportion of boiling water, but decomposed by a larger proportion of water. R. F. Weinland and J. Alfa could not prepare this salt.

E. B. R. Prideaux found that when fluorine acts on tellurium at —78°, white, crystalline **tellurium hexafluoride,** TeF_6, is formed. This melts to a clear, mobile liquid as the temp. rises, and then assumes the gaseous state. The gas has an unpleasant odour recalling that of tellurium hydride and that of ozone. The sp. gr. of the liquid is 3·025 at —35·5°; and the mol. vol., 79·9. The coeff. of expansion of the liquid between —3·5° and 51·5° is 0·032. The m.p. is —36°; and the b.p., —35·5°. The vap. press. of the solid at 35·5° is 760 mm. The critical temp. is 83·25°. The vap. density (oxygen 16) is 119·5, in agreement with a mol. wt. 239 when the calculated value for TeF_3 is 241·6. The refractive index is 1·00091 when the value calculated from the addition rule is 1·001823. The gas does not attack glass; and it is decomposed by water: $TeF_6+4H_2O=H_2TeO_4+6HF$. N. V. Sidgwick discussed this reaction.

The action of chlorine on tellurium has been previously discussed. H. Rose[2] observed that when a slow current of chlorine is passed over strongly heated tellurium, or natural silver telluride, **tellurium dichloride,** $TeCl_2$, accompanied by some tetrachloride, collects as a distillate. The two can be separated by fractional distillation. According to V. Lenher, the dichloride can be prepared by passing the vapour of sulphur monochloride over strongly heated tellurium: $Te+S_2Cl_2=TeCl_2+2S$; the black dichloride soon changes to the white tetrachloride: $TeCl_2+S_2Cl_2=TeCl_4+2S$. K. Lindner and L. Apolant obtained the dichloride by heating tellurium in the vapour of carbonyl chloride; the brown vapours condense to a black crystalline mass. M. Damiens observed no evidence of the existence of the dichloride on the f.p. curve of mixtures of the constituent elements, Fig. 43. Hence, the dichloride is stable only in the gaseous state or in soln. and in equilibrium with its decomposition products—tellurium and tellurium tetrachloride. As it solidifies, it dissociates into a solid soln. of the element in the tetrachloride. J. J. Berzelius, and A. Michaelis heated the mixed di- and tetrachlorides with tellurium in a flask fitted with a reflux condenser for a long time so as to reduce the tetrachloride to the dichloride. Tellurium dichloride is a black, amorphous, hygroscopic solid, which, said H. Rose, does not fume in air; when powdered, it is yellowish-green. A. Michaelis found the vap. density at 444° to be 6·6 to 7·0 (air unity) when the calculated value for $TeCl_2$ is 6·89. A. Michaelis gave 175° for the m.p., and T. Carnelley and W. C. Williams 209°±5°; and for the b.p. 327°, while A. Michaelis gave 324°. W. Herz gave 7·05 for the sp. gr.; 16·6 cals. per gram for the heat of fusion; and $2{\cdot}64\times10^{12}$ for the vibration frequency. The molten liquid is black; and the vapour has a colour not unlike that of iodine, but somewhat paler. The absorption spectrum was studied by D. Gernez, A. Wüllner, and W. Friederichs. When the reddish vapour of sulphur dichloride is heated it becomes paler and then assumes a yellow colour, and like tellurium tetrachloride it then shows no absorption spectrum. A. Voigt and W. Biltz found the electrical conductivity of the dichloride to be 0·042 mho at 206°; 0·0668 mho at 230°; 0·114 mho at 271°; and 0·151 at 305°. W. Biltz gave 0·042 for the temp. coeff. K. T. Compton gave 2·70 volt for the ionizing potential. A. Michaelis found that when the dichloride is heated in oxygen, it decomposes with incandescence forming the tetrachloride and dioxide. Water, acids, and alkali-lye were found by H. Rose to decompose the dichloride forming tellurous acid and tellurium. K. Lindner and L. Apolant said that water converts the dichloride into tellurium and oxydichloride. According to J. J. Berzelius, the same products are obtained when the dichloride is triturated with calcium oxide or sodium carbonate. M. Damiens found that an ethereal soln. of tellurium dichloride absorbs bromide forming which appears to be *tellurium chlorobromide;* and it absorbs iodine forming what may be *tellurium chloroiodide;* but neither substance could be isolated. J. J. Berzelius found that when a mixture of ammonium chloride and an alkali tellurite is heated *ammonium chlorotellurite,* $NH_4Cl.xTeCl_2$, is formed as a black sublimate, and when treated with a small proportion of water, the complex salt turns white owing to the separation of tellurous acid; this acid dissolves completely leaving tellurium behind; with a larger proportion of water, a mixture of tellurium

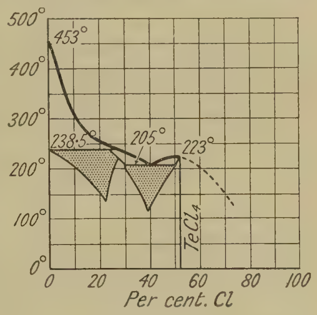

FIG. 43.—Freezing-point Curve of the System: Te–Cl.

and tellurous acid is precipitated. This may be separated by hydrochloric acid, and the water holds in soln. ammonium chlorotellurate and chloride. A. Gutbier and F. Flury—*vide* tellurium dioxide—said that the black sublimate is probably **tellurium diamminodichloride,** $TeCl_2.2NH_3$. K. Lindner and L. Apolant found that the repeated sublimation of the dichloride with a deficiency of ammonium chloride, yields **ammonium tetrachlorotellurite,** $(NH_4)_2TeCl_4$, as a greenish compact mass, which is not hygroscopic, and does not change in air. Tellurium trichloride may be fused with tellurium in all proportions; and when the mixture is heated in a retort, it first gives off tellurium dichloride, then metallic drops of a compound richer in tellurium—this is the only evidence for the existence of a *tellurium subchloride*—*cf.* Fig. 43. The residue left in the retort resembles tellurium, but is more easily powdered and reddens litmus. It is freed from the adherent chlorine by fusion in an atm. of hydrogen, or by boiling first with hydrochloric acid and afterwards with water.

As indicated in connection with tellurium dichloride, when an excess of chlorine acts on heated tellurium, **tellurium tetrachloride,** $TeCl_4$, mixed with some dichloride is formed. J. J. Berzelius, and A. Michaelis separated the mixture by fractional distillation. V. Lenher, and R. W. E. MacIvor also obtained it by passing the vapour of sulphur monochloride over heated tellurium. J. H. Simons also obtained it by distilling off the tetrachloride. Tellurium tetrachloride, at ordinary temp., is a snow-white crystalline mass. J. J. Berzelius found that it melts to an amber-yellow liquid, which becomes dark red near the b.p. A. Weller showed that it is an example of a colourless solid giving a coloured liquid, and vapour for the yellow vapour, said A. Wüllner, shows no absorption spectrum. J. H. Simons showed that the change in the colour of the vapour above 500° is due to the dissociation of the tetrachloride into dark red dichloride. J. H. Simons gave for the sp. gr. of the liquid:

	232°	277°	314°	341°	385°	424°	427°
Sp. gr. .	2·559	2·494	2·443	2·402	2·334	2·275	2·260

A. Michaelis found the vapour density (air unity) at 441° to be 9·03 to 9·22, and at 530°, 8·47 to 8·86. The calculated value for $TeCl_4$ is 9·33. J. H. Simons gave for the vapour density (H_2=2·016):

	420°	450°	480°	507°	522°	561°	601°
Vap. density .	290·3	283·1	277·7	273·2	269·1	260·2	250·5

It is concluded that the vapour consists of single molecules of $TeCl_4$ from the m.p. to about 500° where the dissociation $TeCl_4=TeCl_2+Cl_2$ begins. J. H. Simons gave for the surface tension, σ dynes per cm.:

	238°	260°	280°	316°	352·5°	370°	413·5
σ . . .	40·2	38·3	36·87	34·25	31·57	30·09	26·92

and the parachor ranges from 265·8 to 269·2. The vapour press., p mm.

	233°	260°	278·5°	313°	345°	360°	390°
p . . .	10·8	26·0	45·5	116·7	269·5	396·5	755·6

The results are taken to mean that the molecules of the vapour are associated only to a slight extent. T. Carnelley and W. C. Williams gave 224° for the m.p.; J. H. Simons, 225°; M. Damiens, 223°—Fig. 41; A. Michaelis, 214°. W. Biltz and H. Friedrich, 224°; and R. W. E. MacIvor, 214·5°. T. Carnelley and W. C. Williams gave 414° for the b.p.; J. H. Simons, 390°; and A. Michaelis, 380°—if the compound contains tellurium dioxide as impurity, the b.p. may appear higher. M. Wasilieff discussed the eutectic Te+$TeCl_4$. The heat of vaporization was found by J. H. Simons to be 18,400 cals. per mol. A. Voigt and W. Biltz gave for the electrical conductivity, 0·1145 mho at 236°; 0·161 mho at 271°; 0·203 at 316°; and W. Biltz gave for the temp. coeff. 0·11. J. H. Simons concluded that the molecule consists of a ten-electron shell surrounding a central atom, four parts of these being shared with chlorine atoms. S. Kyropoulos studied the dielectric constants of the crystals.

J. J. Berzelius, and V. Lenher found that the tetrachloride is stable in dry air; but in moist air, it deliquesces to a clear yellow liquid which gradually becomes turbid, and dries with the loss of hydrogen chloride to leave an oxychloride as residue. It dissolves completely in boiling water, and when the soln. cools, crystals of tellurium dioxide, accompanied by a little oxychloride, separate out. The aq. soln. behaves like a soln. of tellurium dioxide in hydrochloric acid. P. E. Browning and W. R. Flint said that in the hydrolysis of the tetrachloride, however large the proportion of water employed when hot, all the tellurous acid is precipitated, that which remains in soln. may be precipitated as dioxide by adding ammonia to the boiling soln., and then acetic acid; and they thought that the fraction remaining in soln. during the hydrolysis was a related dwi-tellurium—*vide supra*. They also showed that if tellurous oxide, freed from telluric oxide, is dissolved in hydrochloric acid which has been exposed to bright sunlight, and the soln. hydrolyzed with boiling water, the precipitate gives no chlorine when boiled with hydrochloric acid. R. Metzner said that tellurium tetrachloride dissolves in conc. hydrochloric acid, and the soln., sat. with hydrogen chloride at —30°, furnishes yellow needles of **tellurium hydropentachloride,** $TeCl_4.HCl$. This melts at —20°. It fumes in air giving off hydrogen chloride. W. Strecker and W. Ebert said that at 0°, white, hygroscopic **tellurium hexamminotetrachloride,** $TeCl_4.6NH_3$, is formed in ammonia gas; if the halide is at —80° the ammonia condensing on the tetrahalide produces a mixture which detonates when heated, presumably owing to the formation of nitrogen telluride (*q.v.*). V. Lenher found that tellurium tetrachloride is sparingly soluble in cold sulphur monochloride, but readily soluble in the hot liquid. C. Whitehead represented the reaction with tellurium hydride by $TeCl_4+2H_2Te=3Te+4HCl$. According to J. J. Berzelius, tellurium tetrachloride mixes with fused tellurium dichloride in all proportions—if the former predominates, the compound is yellow or dark red when liquid, and if the latter predominates, black. A. W. Ralston and J. A. Wilkinson found that at low temp. liquid hydrogen sulphide reduces the tetrachloride to the monochloride, and at ordinary temp., to tellurium. W. Prandtl and P. Borinsky found that sulphur trioxide reacts with tellurium tetrachloride forming the complex $TeCl_4.SO_3$. R. Metzner found that if ammonia be passed over tellurium tetrachloride at 200° to 250°, the colour blackens, owing to the separation of tellurium: $3TeCl_4+16NH_3=3Te+12NH_4Cl+2N_2$. At 0°, ammonia combines with the tetrachloride forming **tellurium triamminotetrachloride,** $TeCl_4.3NH_3$. This compound is not deliquescent; it gives off ammonia at ordinary temp.; it forms tellurous acid when treated with water; and gives off ammonia with alkali-lye. When heated it blackens, giving off ammonia, and at a higher temp. it forms tellurium dichloride, recognizable by the violet fumes. F. Wöhler and R. Espenschied said that even at ordinary temp. the tetrachloride absorbs ammonia forming **tellurium tetramminotetrachloride,** $TeCl_4.4NH_3$, as a voluminous, greenish-yellow mass which is stable in air. It is resolved by water into ammonium chloride and tellurous acid; and when heated is decomposed into tellurium, nitrogen, ammonium chloride, and hydrogen chloride. R. Metzner observed that molten tellurium tetrachloride at 220·5° dissolves phosphorus pentachloride, and furnishes a lemon-yellow crystalline mass of **tellurium phosphotridecachloride,** $2TeCl_4.PCl_5$. This becomes orange-yellow when hot. It forms a colourless liquid with a small proportion of water; but with a larger proportion of water, tellurous acid separates out. It sublimes with partial decomposition in air, but it is not so decomposed in the vapour of phosphorus pentachloride. A. M. Hageman observed that tellurium tetrachloride is soluble in benzene, toluene, methyl alcohol, ethyl alcohol, *n*-butyl alcohol, amyl alcohol, benzyl alcohol, xylene, chloroform, and ethyl acetate; sparingly soluble in light petroleum, benzaldehyde, acetone, *iso*propyl bromide, and carbon tetrachloride; and insoluble in carbon disulphide. According to J. J. Berzelius, the smallest trace of organic matter causes the tetrachloride to turn yellow on melting owing to the formation of some dichloride, which, at a higher temp., escapes as a violet vapour. According to V. Lenher, tellurium tetrachloride forms a complex $(C_2H_5)_2O.TeCl_4$, with ether; and a complex with methylamine. J. F. Norris and R. Mommers obtained a complex with dimethylamine; V. Lenher, complexes with ethylamine, trimethylamine, aniline, pyridine, and quinoline; and V. Lenher and W. Titus, complexes with quinine, cinchonine, morphine, theobromine, brucine, aconite, atropine, strychnine, and cocaine. H. D. K. Drew observed that cyclic condensation products are obtained with diphenyl ether and tellurium tetrachloride in chloroform soln.; G. T. Morgan and R. E. Kellett studied the interaction of the tetrachloride with anisole, etc.; G. T. Morgan and co-workers, monoketones, diketones, and triketones; G. T. Morgan and H. D. K. Drew, ethylene, acetylacetone, and acetic anhydride; G. T. Morgan and H. Burgess, dimethylaniline; and P. Falciola, thiocarbamide. Derivatives of *cyclo*telluripentane and *cyclo*telluropentane were prepared. D. K. Drew showed that $Te(CH_3)_2X_2$ readily passes into $Te(CH_3)_3X.TeCH_3X_3$, where X denotes a halogen atom. This is taken to mean that the compound has a tendency to get away from the unstable ten-electron shell by the association of two molecules to form an eight-electron shell to one tellurium atom, and a twelve-electron shell to the other. According to W. Biltz and K. Friedrich, metallic silver decomposes tellurium tetrachloride forming silver telluride and chloride; the excess of the tetrachloride has no action on silver telluride. Hence in its halogen compounds, tellurium behaves like a noble metal. A. Mazzucchelli and A. Vercillo found that copper furnishes a telluride, but not so with lead.

The higher halides of tellurium are more stable than those of sulphur and selenium. The tetrahalides of tellurium are most stable, whilst with selenium the lower halides are the most stable. The increase of basic properties observed in passing from selenium to tellurium is confirmed by the tellurium forming better-defined double halides. J. J. Berzelius prepared orange-yellow octahedral crystals of **ammonium hexachlorotellurite,** $(NH_4)_2.TeCl_6$, as a precipitate from a soln. of ammonium chloride and tellurium tetrachloride in hydrochloric acid. The salt was also prepared by W. Muthmann, and P. Köthner. C. F. Rammelsberg obtained yellow, cubic crystals of a salt which he represented by the formula $8NH_4Cl.3TeCl_4$, but this salt was probably impure hexachlorotellurite. P. Köthner said that the crystals are difficult to dry without decomposition. J. J. Berzelius said that the salt can be dissolved in a small proportion of water to form a colourless soln., but with a large proportion of water, or alcohol, the salt is decomposed. A. Gutbier prepared a number of complexes of the type $(R.NH_3)_2TeCl_6$ involving organic radicles. J. J. Berzelius, P. Köthner, and H. L. Wheeler obtained **potassium hexachlorotellurite,** K_2TeCl_6, in pale yellow, octahedral crystals from mixed hydrochloric acid soln. of potassium chloride and tellurium tetrachloride or a soln. of tellurium dioxide in hydrochloric acid. The crystals are stable in dry air, but they deliquesce in moist air; water decomposes them with the separation of tellurous acid and tellurium oxychloride. They are soluble in hydrochloric acid; and conc. hydrochloric acid or alcohol precipitates potassium chloride from this soln. C. F. Rammelsberg's formula, $8KCl.3TeCl_4$, is supposed to be based on the analysis of an impure salt. H. L. Wheeler, and P. Köthner likewise prepared **rubidium hexachlorotellurite,** Rb_2TeCl_6, in yellow octahedra, stable in air. H. L. Wheeler found that at 22°, 100 parts of hydrochloric acid of sp. gr. 1·05 dissolve 13·09 parts of the salt, and an acid of sp. gr. 1·2, 0·34 part. By a similar process, H. L. Wheeler prepared **cæsium hexachlorotellurite,** Cs_2TeCl_6, in yellow

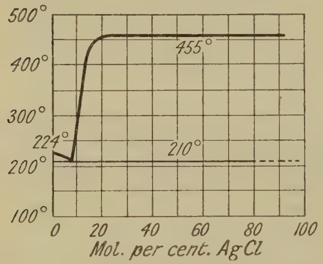

FIG. 44.—Freezing-point Curve of the Binary System: $TeCl_4$–AgCl.

octahedra; he found that at 22°, 100 parts of hydrochloric acid of sp. gr. 1·05 dissolve 0·78 part of the salt, and an acid of sp. gr. 1·2, 0·05 part. W. Biltz and H. Friedrich found that when tellurium tetrachloride is melted in sealed tubes with silver chloride, the liquid separates into two layers when over 20 molar per cent. AgCl is present. The lower liquid is almost all silver chloride and it freezes at 440°–455°; while the upper layer contains a eutectic mixture with the excess of silver chloride. The eutectic at 210° contains about 9 molar per cent. of AgCl—Fig. 44. No *silver tellurium chloride* is formed. R. Weber heated a mixture of aluminium trichloride and tellurium tetrachloride in a sealed tube, and drove off the excess of the former, by the application of a stronger heat, and there remained **aluminium decachlorotellurite,** $2AlCl_3.TeCl_4$. This compound is decomposed at an elevated temp.; it is hydrolyzed by water with the separation of tellurous acid; and it dissolves completely in dil. sulphuric acid.

J. J. Berzelius [3] said that bromine unites with tellurium at ordinary temp. with the development of heat; and he obtained **tellurium dibromide,** $TeBr_2$, by sublimation from a mixture of tellurium and its tetrabromide. The dibromide appears as a greenish-black crystalline mass, or in needle-like crystals. The powder is yellowish-olive-green. J. J. Berzelius said that the vapour is dark violet; and, according to D. Gernez, its absorption spectrum has lines in the red and yellow. Tellurium dibromide was found by T. Carnelley and W. C. Williams to melt at approximately 280°; B. Brauner said approximately 210°; and, added J. J. Berzelius, the cold mass has no marked lustre, or crystalline fracture. T. Carnelley and W. C. Williams gave 339° for the b.p. at 760 mm.; and B. Brauner gave 280° in vacuo, and added that sublimation in vacuo begins at about 200°. As in the case of tellurium dichloride, the observations of M. Damiens, Fig. 45, show that as the compound solidifies it dissociates into a solid soln. of tellurium in the tetrabromide. B. Brauner found that the dibromide is decomposed by water: $2TeBr_2=Te+TeBr_4$; and in moist air, this change rapidly occurs. A conc. soln. of tartaric acid dissolves a part of the dibromide forming a greenish-brown soln. from which water precipitates tellurium.

According to J. J. Berzelius, **tellurium tetrabromide,** $TeBr_4$, is prepared by introducing bromine into a glass tube, sealed at one end, and cooled by immersion in ice, adding powdered tellurium, not in excess, with frequent stirring; the excess of bromine is removed by heating the mixture on a water-bath. B. Brauner removed the excess of bromine by a current of carbon dioxide; unchanged tellurium was removed by heating the mixture which converted the tellurium into volatile dibromide; and oxybromide was removed by sublimation in vacuo at 300°. C. von Hauer prepared the tetrabromide by adding bromine to a mixture of tellurium and dil. hydrobromic acid, until the tellurium dissolved; the ruby-red liquid was then evaporated on a water-bath. F. A. Gooch and A. W. Peirce warmed tellurium dioxide with an aq. soln. of potassium bromide and phosphoric acid; on concentrating the soln., ruby-red crystals of tellurium tetrabromide are formed.

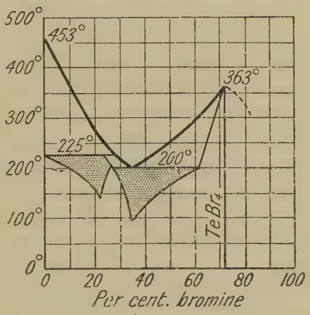

FIG. 45.—Freezing-point Curve of the System: Te–Br.

Tellurium tetrabromide, when obtained by sublimation, furnishes dark yellow prisms when slowly cooled, and fiery red or orange-red when rapidly cooled. B. Brauner found the sp. gr. to be 4·310 at 15°/4°. T. Carnelley and W. C. Williams gave 380° ± 6° for the m.p. J. J. Berzelius said that the molten liquid is dark red, and it forms a crystalline mass on solidification. M. Damiens gave 363° for the m.p.—Fig. 45. T. Carnelley and W. C. Williams found the b.p. to be 414° to 427°. J. J. Berzelius added that the vapour is yellow, and condenses to a yellow powder, needle-like crystals, etc. B. Brauner said that the tetrabromide cannot be melted or boiled under ordinary atm. press. without partial decomposition into tellurium dibromide. G. Beck studied the heat of soln. in water. S. Kyropoulos measured the dielectric constants of the crystals.

According to J. J. Berzelius, tellurium tetrabromide slowly absorbs moisture when exposed to air, and it dissolves without apparent decomposition in a small proportion of water; with a large proportion of water, the yellow liquid is resolved into tellurous and hydrobromic acids—the former appears as a precipitate. If the soln. in a small proportion of water is evaporated, it furnishes dark ruby-red, rhombic plates which, when dried, become yellow and earthy. B. Brauner found that the tetrabromide is soluble in an aq. soln. of tartaric acid (1 : 1), and the orange-yellow soln. can be diluted with water without separation owing to the formation of tellurium tartrate, tellurous acid, however, separates with a very dil. soln. of tartaric acid. According to R. Metzner, tellurium tetrabromide unites with hydrobromic acid with the evolution of heat; when the soln. is cooled to —15°, it furnishes orange-red, needle-like crystals of **tellurium hydropentabromide,** $TeBr_4.HBr.5H_2O$, which can be drained on a porous tile, and dried in dry air. The crystals melt at 20°, giving off hydrogen bromide. The crystals can be kept a long time at a low temp. in an atm. of hydrogen bromide; they are very deliquescent in air, and give off hydrogen bromide. W. Prandtl and P. Borinsky found that sulphur trioxide reacts with the tetrabromide forming $TeOH_2.SO_3$. According to W. Strecker and W. Ebert, the tetrabromide reacts with ammonia forming what is probably **tellurium hexamminotetrabromide,** $TeBr_4.6NH_3$, which then decomposes into nitrogen telluride (*q.v.*). V. Lenher observed that tellurium tetrabromide forms complex salts with methylamine, trimethylamine, ethylamine, aniline, pyridine, and quinoline; J. F. Norris and R. Mommers obtained a complex with dimethylamine; and V. Lenher and W. Titus, with quinine, cocaine, brucine, and morphine. A. Lowy and R. F. Dunbrook studied its action on primary, secondary, and tertiary amines; and E. H. Rusk, on phenols, and phenol ethers.

A number of **bromotellurites** has been prepared. W. Muthmann prepared **ammonium hexabromotellurite,** $(NH_4)_2TeBr_6$, from a soln. of ammonium bromide and tellurium dioxide in hydrobromic acid. The dark red, octahedral crystals are less soluble than the potassium salt. A. Gutbier and F. Flury prepared a number of complexes of the type $(R.NH_3)_2TeBr_6$ involving organic radicles. J. J. Berzelius prepared **potassium hexabromotellurite,** K_2TeBr_6, from a soln. of potassium chloride in one of tellurium bromide. C. von Hauer said that the product is contaminated with chloride, and he obtained the salt by adding bromine to a soln. of potassium bromide mixed with tellurium until that element had all dissolved. H. L. Wheeler used an excess of hydrobromic acid to prevent the precipitation of tellurous acid. The anhydrous salt separates from the boiling soln. in dark red octahedral crystals, which, according to W. Muthmann, are isomorphous with the corresponding bromoselenite. H. L. Wheeler found that the dihydrate, $K_2TeBr_6.2H_2O$, is formed by the evaporation of the aq. soln. at ordinary temp. C. von Hauer thought the salt is trihydrated, but H. L. Wheeler said that extra water in the latter case is present as inclusions. According to C. von Hauer, the dark red, opaque crystals resembling octahedra, belong to the rhombic system, for which W. J. Grailich and V. von Lang obtained the axial ratios $a : b : c = 0{\cdot}6857 : 1 : 0{\cdot}9415$; and H. Baker, $0{\cdot}6711 : 1 : 0{\cdot}9167$. The optical character is negative; there is no marked cleavage. The crystals effloresce superficially in dry air; and C. von Hauer found that they lose their water of crystallization at 120°, without melting; the dehydrated salt is orange-red. At a higher temp., tellurium tetrachloride is given off. J. J. Berzelius, C. von Hauer, and W. L. Wills observed that the salt dissolves in a small proportion of water, but if the soln. be diluted, tellurous acid is precipitated. H. L. Wheeler found that the salt can be recrystallized from dil. hydrobromic acid; and that at 22°, 100 parts of this acid of sp. gr. 1·08 dissolve 62·90 parts of salt, while with an acid of sp. gr. 1·49 there are 6·57 parts dissolved. J. J. Berzelius said that the salt is decomposed by alcohol. H. L. Wheeler prepared **rubidium**

hexabromotellurite, Rb_2TeBr_6, in an analogous manner. The red octahedral crystals are stable in air; they dissolve in a small proportion of hot water, and on cooling tellurous acid crystallizes out. At 22°, 100 parts of hydrobromic acid of sp. gr. 1·08 dissolve 3·08 parts of salt, and 0·25 part is dissolved by an acid of sp. gr. 1·49. Red octahedral crystals of **cæsium hexabromotellurite,** Cs_2TeBr_6, are obtained in a similar way. At 22°, 10 parts of hydrobromic acid of sp. gr. 1·08 dissolve 0·13 part of salt, and 0·02 part is dissolved by an acid of sp. gr. 1·49. P. Maier studied the crystallography of aliphatic bromotellurites.

Tellurium can be melted with iodine in all proportions, and, added J. J. Berzelius,[4] if the tellurium be in excess, the product has a metallic appearance, while if the iodine be in excess, the product is somewhat soluble in water. J. J. Berzelius found that when a gram-atom of tellurium is heated with more than a gram-atom of iodine, the excess of iodine passes off; and **tellurium diiodide,** TeI_2, sublimes in black, crystalline flakes having some metallic lustre, the fused mass readily sublimes, and the mass obtained by cooling the fused compound has a non-crystalline fracture. When digested with aq. hydrochloric acid, or aq. ammonia, it leaves a residue of tellurium; it is not attacked even by boiling water. A. Gutbier said that when tellurium and iodine are fused together in the requisite proportion to form tellurium diiodide, TeI_2, a black substance is produced which possesses a metallic lustre and melts easily. When very carefully heated, it can be sublimed, but its composition does not appear to be constant.

F. M. Jäger and J. B. Menke studied the f.p. curve of mixtures of the two elements. Tellurium tetraiodide was the only compound observed, and the molten substance is considerably dissociated. There is a eutectic on the tellurium side at 165° and 41 per cent. of tellurium, and this is near the composition required for tellurium di-iodide; on the iodine side, the eutectic at 108° is very near the iodine axis. Solid soln. are not formed to any appreciable extent, and there is no evidence of the formation of a *tellurium periodide*, or *tellurium hexaiodide*, which J. J. Berzelius said is formed when a piece of tellurium is dropped into molten iodine, after shaking the mixture, and decanting the liquid from the undissolved tellurium. The product was said to dissolve sparingly in water forming a dark brown liquid which is decolorized by ammonium sulphite, and which deposits tellurium on adding hydrochloric acid. M. Damiens f.p. curve of mixtures of iodine and tellurium is in general agreement with that of F. M. Jäger and J. B. Menke, and it is illustrated by Fig. 46. F. Olivari studied the effect of tellurium on the f.p. of iodine, and accordingly inferred that with about 94 per cent. of tellurium, the mol. wt. of tellurium is 159 to 171·2—the theoretical value for Te=127·6. E. Beckmann and R. Hanslian also found that cryoscopic and ebullioscopic measurements of soln. of tellurium in iodine indicate a large proportion of single atoms. R. Wright's measurements of the vap. press. of soln. of iodine and tellurium gave no indication of solid soln. or of the formation of any compound other than the tetraiodide.

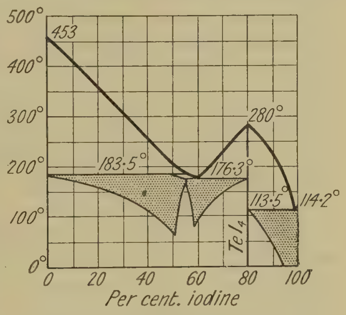

FIG. 46.—Freezing-point Curve of the System: Te–I.

J. J. Berzelius prepared **tellurium tetraiodide,** TeI_4, by digesting tellurium powder for a considerable time with iodine and water; and evaporating the clear liquid which gives off the excess of iodine and leaves a small proportion of the tetraiodide as residue. He also found that by digesting tellurium dioxide with hydriodic acid, in a closed vessel, it is slowly converted into the iron-grey tetraiodide. A small quantity of the tetraiodide dissolves in the excess of hydriodic acid imparting to it a dark brown colour, and may be separated from it in iron-grey prisms, by evaporation in vacuo over sulphuric acid and calcium oxide which takes up the excess of iodine and hydriodic acid. According to A. Gutbier and F. Flury, hydriodic acid acts on telluric acid in two ways. In dil. soln., reduction takes place slowly to tellurium dioxide, and after some time, a dark, granular mass of tellurium tetraiodide, TeI_4, separates. No indication was obtained of the formation of a di-iodide. In conc. soln., the reaction takes place quickly and tellurium tetraiodide is at once precipitated as a heavy iron-grey substance. Tellurium tetraiodide forms a dark-grey powder, or iron-grey prismatic crystals which melt when heated, and, according to A. Gutbier and F. Flury, it is at the same time decomposed. F. M. Jäger and J. B. Menke gave 259° for the m.p.; and M. Damiens, 280°. When boiled, the tetraiodide gives off at first iodine and the distillate becomes richer in tellurium until what was thought to be *tellurium subiodide* remained. The subiodide is probably tellurium contaminated with iodine.

J. J. Berzelius said that the tetraiodide is resolved by water into an oxyiodide which retains the form of the tetraiodide, and hydriodic acid holding a little tellurium tetraiodide in soln. Cold water has but a slight decomposing action and remains colourless, taking up only a small proportion of hydriodic acid; boiling water acquires a dark brown colour, and forms an oxyiodide. A. Gutbier and F. Flury said that the tetraiodide is decomposed by water: $TeI_4+2H_2O=4HI+TeO_2$, and a similar decomposition occurs with alcohol. The tetraiodide dissolves in aq. ammonia; it also dissolves in alkali-lye. According to J. J. Berzelius, when a sat. soln. of tellurium tetraiodide in conc. hydriodic acid is evaporated in vacuo over sulphuric acid, long, rectangular, four-sided prisms are obtained having a metallic lustre. R. Metzner obtained a similar product, **tellurium hydropentaiodide,** $TeI_4.HI.8$ or $9H_2O$, by passing hydrogen iodide into a soln. of tellurous acid in hydriodic acid. J. J. Berzelius said that in a sealed glass tube the crystals melt to a dark brown liquid which solidifies on cooling; and in an open vessel, at 50° to 60°, they do not melt, but give off brown fumes of hydrogen iodide decomposed by contact with air, and leave a residue of tellurium tetraiodide. R. Metzner said that when heated out of contact with air, the crystals melt at —55°, and solidify without chemical change on cooling; at a higher temp., they lose first water and then hydrogen iodide. The compound is decomposed by water yielding a precipitate of tellurium tetraiodide.

Tellurium tetraiodide unites with the iodides of the alkali metals forming **iodotellurites.** J. J. Berzelius prepared **ammonium hexaiodotellurite,** $(NH_4)_2TeI_6$, from a soln. of tellurium tetraiodide in hydriodic acid, neutralized with ammonia. The spontaneous evaporation of the liquid furnishes steel-grey octahedral crystals soluble in water and in absolute alcohol. J. J. Berzelius also reported that hydrated **sodium iodotellurite** crystallizes from an aq. soln. of the component salts, but this has not been confirmed. J. J. Berzelius prepared **potassium hexaiodotellurite,** $K_2TeI_6.2H_2O$, in a similar manner. The black prismatic crystals were found by H. L. Wheeler to belong to the monoclinic system, and to have the axial ratios $a:b:c=0{\cdot}7047:1:0{\cdot}5688$, and $\beta=120°\ 53°$. The crystals lose their water of crystallization, without decomposition, at 100° to 115°. They effloresce superficially in dry air. J. J. Berzelius added that they form a brown soln. with a small proportion of water, and are decomposed by a larger proportion of water. H. L. Wheeler similarly prepared **rubidium hexaiodotellurite,** Rb_2TeI_6, in microscopic octahedral crystals which are stable in air; and which are slowly decomposed by cold water, rapidly by hot water with the separation of tellurium dioxide and an oxyiodide. They dissolve in a small proportion of alcohol. H. L. Wheeler also prepared **cæsium hexaiodotellurite,** Cs_2TeI_6, as a black, amorphous precipitate which gradually loses iodine when exposed to air, and which melts at a little over the b.p. of sulphuric acid. It behaves like the rubidium salt towards water and alcohol.

§ 13. The Oxyhalides of Tellurium

According to A. Ditte[1] tellurium dioxide absorbs hydrogen fluoride with the development of heat. A. Metzner observed that tellurium dioxide dissolves in 43 to 55 per cent. hydrofluoric acid and on cooling to —20°, long, transparent crystals of **tellurium hexoxyoctofluoride,** $2TeF_4.3TeO_2.6H_2O$, separate. These crystals decompose when heated in hydrogen forming tellurium tetrafluoride, and fluoriferous tellurium dioxide ; they are decomposed by water : $2TeF_4.3TeO_2.6H_2O = 5TeO_2 + 8HF + 2H_2O$. E. B. R. Prideaux and J. O'Neil Millott did not obtain this product in their study of the action of hydrofluoric acid on tellurium dioxide. They measured the solubilities of tellurium dioxide in aq. hydrofluoric acid at 10°, and found that with the following concentrations in grms. per 100 grms. of HF and of TeO_2,

[HF] .	0·221	1·22	7·83	10·0	13·0	15·8	17·5	22·6
[TeO_2]	0·120	1·26	16·8	24·0	44·5	46·2	50·2	43·0
[HF] .	20·5	15·2	16·5	14·8	18·2	24·0	26·4	28·5
[TeO_2]	59·0	54·0	55·7	57·0	50·5	42·6	45·7	58·0

The results with the concentrations expressed in mols of the constituent per 100 mols of soln. are plotted in Fig. 47. The addition of tellurous acid, $H_2TeO_3 \rightleftharpoons H^{\cdot} + HTeO'_3$, to hydrofluoric acid represses the ionization of the hydrofluoric acid, $H_2F_2 \rightleftharpoons H^{\cdot} + HF_2'$, and removes it as a complex ion of the complex fluoride : $2H^{\cdot} + HTeO_3' + HF_2' \rightleftharpoons 2H^{\cdot} + TeF_2O_2'' + H_2O$; and the acid then crystallizes from the aq. soln. as the dihydrate : $2H_2[TeO_2F_2] \rightarrow 2(TeOF_2.H_2O) = TeF_4.TeO_2.2H_2O$. R. Metzner found that when the mother-liquor obtained in the preparation of this salt just described is more strongly cooled, with frequent stirring, needle-like crystals of **tellurium oxydifluoride,** $TeF_2.TeO_2.2HF$, *i.e.* $2TeO_2.4HF$, or **telluryl difluoride,** $TeOF_2.H_2O$, are formed. E. B. R. Prideaux and J. O'Neil Millott preferred the formula $TeF_4.TeO_2.H_2O$, and were unable to decide whether to write it $2TeOF_2.H_2O$, or $TeOF_2TeO_2.2HF$. A. J. Högbom, and E. B. R. Prideaux and J. O'Neil Millott obtained crystals of the oxyfluoride by evaporating an aq. soln. in vacuo over conc. sulphuric acid. R. Metzner found that when the salt is heated, it yields tellurium dioxide and hydrogen fluoride ; and that it is decomposed by water.

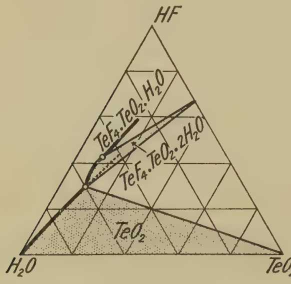

FIG. 47.—The Ternary System : $HF–TeO_2–H_2O$ at 10°.

R. F. Weinland and J. Alfa said that conc. hydrofluoric acid reacts with potassium tellurate forming **potassium difluotellurate,** $K_2TeO_3F_2.3H_2O$, in which an atom of oxygen is replaced by two atoms of fluorine ; but it may also be represented $K_2TeO_4.2HF.2H_2O$. It is obtained by evaporating a soln. of a mol of telluric acid and 2 mols of potassium hydroxide to dryness on the water-bath and dissolving the residue in a slight excess of hydrofluoric acid ; it crystallizes in microscopic, octahedral, monoclinic crystals, is fairly stable in dry air, but when heated evolves water and a small quantity of hydrogen fluoride, or at a higher temp. oxygen, and leaves a residue of tellurium dioxide and potassium fluoride. It is difficult to dissolve in water, yielding a faintly acid soln. and cannot be recrystallized from hydrofluoric acid. The corresponding **rubidium difluotellurate,** $Rb_2TeO_3F_2.3H_2O$, similarly prepared, furnishes colourless crystals rather more soluble than the potassium salt. Neither *ammonium difluotellurate,* nor *sodium difluotellurate* could be prepared.

J. J. Berzelius obtained a number of **tellurium oxychlorides** of undetermined composition—*e.g.* by the action of cold water on tellurium tetrachloride; from a soln. of the tetrachloride in boiling water; by exposing the tetrachloride to moist air; by evaporating a soln. of the tetrachloride on the water-bath; by dissolving the tetrachloride in hydrochloric acid, by evaporating a hydrochloric acid soln. of telluric acid; and from a soln. of tellurium in aqua regia. A. Michaelis obtained oxychlorides from a soln. of tellurium dioxide in molten tellurium tetrachloride. According to A. Ditte, tellurium dioxide readily absorbs hydrogen chloride with the development of heat and the formation of a brown mass. If the temp. be below —10°, the product has the composition *tellurium dioxytrihydrotrichloride,* $TeO_2.3HCl$; by slightly raising the temp. *tellurium dioxydihydrodichloride,* $TeO_2.2HCl$, is formed, and this can be heated to 90° without decomposition. T. W. Parker and P. L. Robinson observed no evidence of the formation of a complex $TeO_2.n.HCl$ in the range of temp. 0° to 150°. At 0°, hydrogen chloride is absorbed to form a heterogeneous product which loses water continuously in a stream of gas as the temp. is raised. At about 110°, it melts to a brown liquid forming **tellurium oxydichloride,** or **telluryl dichloride,** $TeOCl_2.H_2O$, and the reaction is completed at 300°. If heated to a still higher temp., the oxydichloride is decomposed into tellurium tetrachloride and dioxide: $2TeOCl_2=TeO_2+TeCl_4$. V. Lenher also prepared the complex $TeO_2.2HCl$, but showed that it is not converted into the oxydichloride by heat but rather into a mixture of the tetrachloride and dioxide without the intermediate formation of an oxydichloride. If the tetrachloride and dioxide are heated together, no combination occurs, and on cooling the original compounds can be removed unchanged. K. Lindner and L. Apolant said that the oxydichloride is formed, with the separation of tellurium, by the action of water on tellurium dichloride.

J. J. Berzelius obtained tellurium **oxybromides** of undetermined composition—*e.g.* by exposing **tellurium** tetrabromide to moist air; and by the action of water on the tetrabromide. A. Ditte found that tellurium dioxide at ordinary temp. absorbs hydrogen bromide with the development of heat forming a dark brown, crystalline mass which at —14° absorbs more of the gas to form a black, crystalline mass of *tellurium dioxytrihydrotribromide,* $TeO_2.3HBr$; if the temp. be raised not over 40°, this passes into tellurium dioxydihydrodibromide, $TeO_2.2HBr$, which begins to lose water when heated to 70°, and forms **tellurium oxydibromide** or **telluryl bromide,** $TeOBr_2$, when heated up to 300°. At a higher temp., the pale yellow mass melts and decomposes $2TeOBr_2=TeO_2+TeBr_4$.

J. J. Berzelius obtained **tellurium oxyiodides** of undetermined composition—by boiling tellurium tetraiodide with successive quantities of water; by evaporating a sat. soln. of the tetraiodide in conc. hydriodic acid; and from a soln. of telluric acid in hydriodic acid. A. Ditte found that tellurium dioxide absorbs hydrogen iodide at —15°, but at ordinary temp., the dioxide is decomposed. The absorption at —15° is very slow because the dioxide agglomerates together. He was unable to fix as much as one eq. of the hydrogen iodide with the tellurium dioxide; and as the temp. rises, the product decomposes forming tellurium iodide.

§ 14. Tellurium Sulphides

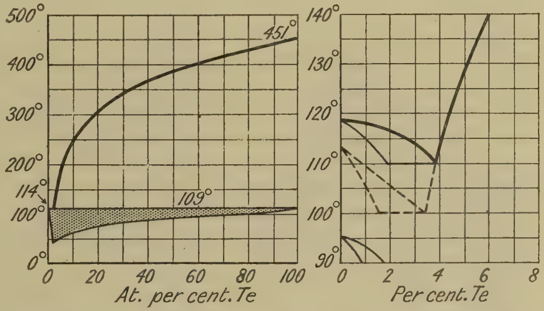
According to J. J. Berzelius,[1] H. Rose, F. Becker, B. Brauner, L. Staudenmaier, A. M. Hageman, and A. Gutbier and F. Flury, the precipitate produced by hydrogen sulphide in a hydrochloric acid soln. of tellurium dioxide in hydrochloric acid, or an acidified soln. of an alkali tellurite, is unstable **tellurium disulphide,** TeS_2. M. Chikasige also said that the alleged disulphide is really a mixture. When first formed, the precipitate is red, but it very quickly turns brown, brownish-black, and finally black, owing to the decomposition of the sulphide into its elements; and if the dried precipitate be extracted with carbon disulphide, all but 1 to 4 per cent. of the sulphur can be removed. B. Brauner thought that the sulphur so retained was evidence that a more stable sulphide is associated with the ordinary disulphide, but F. Becker, A. H. Hageman, and L. Staudenmaier said that the sulphur is very intimately mixed with the tellurium and inaccessible to the solvents; and is not present as tellurium sulphide decomposable by hydrochloric acid or as a variety of sulphur insoluble in carbon disulphide. A. M. Hageman found that at temp. below —20°, tellurium disulphide is stable, but above —20° dissociation sets in; and at —20° dissociation is slow, and becomes more rapid as the temp. is raised. The progress of the dissociation can be measured by the proportion of sulphur extracted by carbon disulphide, but the reaction is never complete—at least 0·95 per cent. of sulphur remains. The production of tellurium disulphide is independent of the conc. of the acid, and of the medium in which the reaction is effected—*e.g.* ether, and other organic solvents can be used instead of water as solvent. The dissociation and stability of the disulphide is solely a question of temp. A. Gutbier and F. Flury suggested that the precipitate at the moment of the formation is *sulphotellurous acid*, H_2TeS_3, or the complex $H_2TeS_3.2H_2S$. A. Gutbier found that a pseudo-solution, or a soln. of **colloidal tellurium disulphide** is formed as a transparent liquid with a blue fluorescence. After dialysis, the sol. keeps well; and by freezing, a solid hydrosol is produced. R. Astfalk also investigated the colloidal disulphide.

The bluish-black product, alleged to be the disulphide, TeS_2, according to J. J. Berzelius, acquires a metallic lustre when burnished. It softens when heated without melting completely; swells up; and solidifies on cooling to form a blistered, grey mass. When heated in a retort, sulphur distils off leaving a residue of tellurium; a mixture of the product with a metal sulphide leaves a residue of the metal telluride. The alleged tellurium disulphide forms a yellow soln. with boiling alkali-lye; and when freshly precipitated, dissolves sparingly in conc. aq. ammonia. R. W. E. MacIvor said that the fresh precipitate dissolves in a soln. of ammonium sulphide, but owing to the decomposition of the disulphide, some tellurium remains undissolved.

W. O. Snelling said that at the moment of precipitation of tellurium sulphide by hydrogen sulphide in an aq. soln. of tellurous acid, only half the sulphur is soluble in carbon disulphide, and that the insoluble residue consists of **tellurium monosulphide,** TeS, supposed to be formed in accord with: $2H_2S+H_2TeO_3=TeS+S+3H_2O$. This compound is said to be very unstable and to decompose completely in about 4 hrs. at 0°, and much more rapidly at higher temp. A. M. Hageman said that the alleged monosulphide has no existence.

According to J. J. Berzelius, if a dil. aq. soln. of telluric acid be sat. with hydrogen sulphide, and set aside in a closed vessel in a warm place, it turns brown without losing its colour; afterwards the colour disappears, and **tellurium trisulphide,** TeS_3, is deposited as a greyish-black, shining film which is easily rubbed off in flakes. According to F. Becker, B. Brauner, and A. Gutbier and F. Flury, the precipitate has the composition Te : 3S, and during its formation some telluric acid is reduced to tellurous acid. A. Gutbier and F. Flury added that there is no sign of the formation of a *sulphoxytelluric acid*. B. Brauner, and F. Becker found that the alleged tellurium trisulphide gives up nearly all its sulphur to carbon disulphide—F. Becker found about 6·15 per cent. escaped extraction. B. Brauner said that the sulphur is completely volatilized when the trisulphide is heated in a current of an indifferent gas. He observed that telluric acid resembles arsenic acid, but it surpasses it in so far as it is acted on by that reagent with far greater difficulty. It is also far more difficult to reduce by sulphurous acid. It differs from arsenic acid in so far as no *sulphoxytelluric acid* is formed in the cold. It resembles antimonic acid in the arrangement of atoms corresponding with the formation of a sulphoxytelluric acid being very unstable, but it differs from it in that if the acid in question is formed at a high temp. it is immediately destroyed. Tellurium differs, however, most essentially both from arsenic and from antimony, in the fact that tellurous acid and telluric acid when precipitated with hydrogen sulphide, give, as a final product of the action, precipitates consisting almost entirely of free tellurium and of free sulphur in the at. proportions $Te+S_2$ or $Te+S_3$. It is therefore impossible to investigate the question whether telluric acid, when treated with hydrogen sulphide under certain conditions, gives the disulphide, and under other conditions the trisulphide, in the same way as could be done with arsenic and antimony, for their sulphides are relatively stable. A. Gutbier found that when a small proportion of hydrogen sulphide is passed into a dil. soln. of telluric acid, a soln. of colloidal tellurium trisulphide is formed. It is steel-blue to violet by transmitted light.

J. J. Berzelius stated that tellurium and sulphur may be melted together in all proportions—with an excess of sulphur, the mixture is yellowish-red; as the proportion of tellurium is increased, the mixture appears red by transmitted light, and black by reflected light; and with a still higher proportion of tellurium, an opaque, lead-grey mixture is produced. G. Pellini showed that the f.p. curves furnish no indication of the formation of a compound, but a series of mixed crystals may be obtained both by fusion and by soln. Some of these crystals are isomorphous with rhombic sulphur, Figs. 1 and 2, for instance, those containing 0·557 per cent. of tellurium, have the axial ratios $a:b:c=0{\cdot}8136:1:1{\cdot}86929$, while artificial sulphur crystals have the ratios 0·8108 : 1 : 1·9005. A solid amorphous soln. of tellurium and sulphur was obtained which is insoluble in carbon trisulphide. The red sulphur of Japan is said to be an isomorphous mixture of sulphur, selenium, and tellurium. The f.p. curves of mixtures of sulphur and selenium, and of selenium and tellurium have been discussed in connection with selenium sulphide and tellurium selenide. G. Pellini's observations on sulphur and tellurium are illustrated in Figs. 48 and 49. Fig. 49 shows an enlargement of the f.p. curves in the vicinity of the eutectic. M. Chikashige found that two series of solid soln. are formed of limited concentration and the eutectic given by M. Chikashige is at 109° and 7 per cent. of tellurium. F. M. Jäger gave 106° for the eutectic. According to M. Chikashige, the transformation temp. of sulphur at 120° and 94·5° are lowered by tellurium. Whilst β-sulphur retains 2 per cent. of tellurium in solid soln., α-sulphur retains only 0·5 per cent., but the separation of the excess occurs only under the influence of light. Molten β-sulphur dissolves 10 per cent. of tellurium, and molten γ-sulphur, 20 per cent. Solid soln. with less than 0·5 per cent. of tellurium—including Japanese red sulphur—are not sensitive to light. The supersaturated crystals containing from 0·5 to 2·0 per cent. of tellurium change from red to yellow or brown when exposed to light; the most active rays have a wave-length $\lambda=4500$. The decomposed portions are more readily dissolved by



Figs. 48 and 49.—Fusion Curve of Mixtures of Sulphur and Tellurium.

carbon dioxide than the original crystals. L. Losana confirmed G. Pellini's value of 1·9 per cent. for the limit of complete miscibility, and he found the minimum on the liquid curve was at 6 per cent. tellurium and the maximum eutectic arrest corresponds with this. When over 97·6 per cent. of tellurium is present, there is no trace of an arrest showing that there is a zone of solid soln. with 98 to 100 per cent. tellurium. L. Losana found that the ternary system exhibits formation of neither compounds nor ternary eutectics, but contains two zones of complete miscibility in which there exist mixed crystals of selenium and tellurium in sulphur and mixed crystals of sulphur and tellurium in selenium. The formation of mixed sulphur-tellurium crystals is favoured by the presence of selenium, which causes solid soln. with high proportions of tellurium to be formed; many of such solid soln. exhibit, however, the phenomenon of more or less rapid unmixing. The first transformation point of sulphur is depressed considerably by selenium and tellurium separately and to a still greater extent by the two elements together. L. Losana's observations are summarized in Figs. 50, 51, and 52. According to L. Amaduzzi and M. Padoa, mixtures of sulphur and selenium are devoid of photo-electric properties.

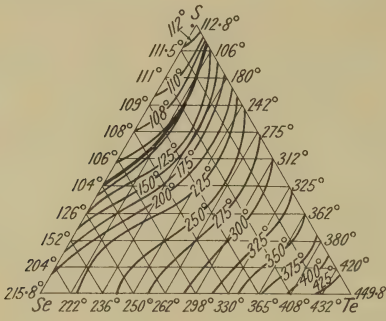


FIG. 50.—Liquidus Curves in the Ternary System: Se–S–Te.

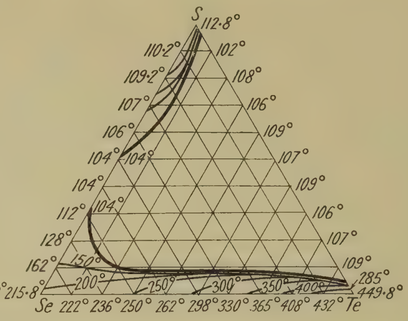

FIG. 51.—Solidus Curves in the Ternary System: Se–S–Te.

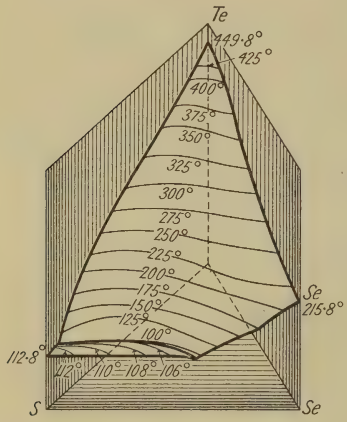

FIG. 52.—Projection of the Liquidus Curves in the Ternary System: Se–S–Te.

A. Stock and P. Praetorius observed that when an arc is maintained under carbon disulphide between a graphite cathode and an anode of tellurium and graphite (10 : 1), the anode is disintegrated, and a reddish-brown soln. is produced in which black particles of tellurium and graphite are suspended. The soln. contains non-volatile decomposition products of carbon disulphide, and carbon subsulphide, (C_3S_2), and **carbon sulphotelluride,** CSTe, which are volatile in the vapour of carbon disulphide. Part of the carbon subsulphide can be removed by fractional distillation; and the remainder by transforming it into a non-volatile thiomalono-naphthylamide by treatment with β-naphthylamine. The dil. soln. was concentrated on a water-bath, and subsequently cooled below —30° when the sulphotelluride was obtained in yellowish-red crystals with a penetrating odour of garlic. If it be smelled for a short time, the breath retains a strong odour of garlic for a considerable time. Cryoscopic and ebulliscopic measurements in benzene or carbon disulphide soln. are in agreement with the formula CSTe. The sp. gr. of the crystals at —50° is 2·9, and the vap. press. at 10° is about 2 mm. The crystals melt at —54° to a brilliant red liquid with a high refractive power. Carbon sulphotelluride, either solid or in soln., becomes blood-red, then black, and decomposes rapidly on attaining room temp. Some decomposition occurs even at —50°. When the soln. in carbon disulphide is treated with bromine, it gives a precipitate of tellurium tetrabromide; and mercury extracts all the compound from its soln. Carbon sulphotelluride is the compound which was previously thought to be carbon ditelluride (*q.v.*).

Salts of the hypothetical *sulphotellurous acid*, H_6TeS_5, have been prepared, as **sulphotellurites.** J. J. Berzelius said that the sulphotellurites of the alkali metals and magnesium are produced by saturating the soln. of the corresponding tellurite with hydrogen sulphide: $3R_2TeO_3+9H_2S=R_6TeS_5+2Te+4S+9H_2O$; they are also produced by the action of a boiling soln. of the alkali hydrosulphides on tellurium dioxide; and by dissolving tellurium disulphide in alkali-lye: $5TeS_2+18KOH=3K_2TeO_3+2K_6TeS_5+9H_2O$. The salts of the alkaline earths and of the heavy metals can be produced by double decomposition of a salt of these elements with the alkali sulphotellurite. The alkali sulphotellurites are brownish-yellow when anhydrous, and pale yellow when hydrated. They can be heated to redness without decomposition if protected from air. The sulphotellurites of the heavy metals are decomposed when heated out of contact with air, forming a metal telluride and basic sulphide. The sulphotellurites are fairly stable in air; freely soluble in water. The aq. soln. decomposes rapidly in air forming a soluble thiosulphate and precipitating a mixture of sulphur and tellurium. The salts dissolve in alcohol with partial decomposition. Acids precipitate tellurium disulphide. J. J. Berzelius reported that **ammonium sulphotellurite,** $3(NH_4)_2S.TeS_2$, or $(NH_4)_6TeS_5$, separates when a soln. of ammonium tellurite is sat. with hydrogen sulphide, and evaporated in vacuo over potassium carbonate. The pale yellow, four-sided prisms lose ammonium hydrosulphide when exposed to air. L. Staudenmaier said that the salt is completely decomposed when confined over sulphuric acid. J. J. Berzelius made pale yellow, amorphous **lithium sulphotellurite,** presumably Li_6TeS_5, by saturating a soln. of lithium carbonate in tellurous acid with hydrogen sulphide, and evaporating the filtered liquid in vacuo. It decomposes easily in air. He also prepared **sodium sulphotellurite,** Na_6TeS_5, in an analogous way; and A. Gutbier and F. Flury, as indicated above, prepared $Na_2TeS_3.2H_2S$, by the action of hydrogen sulphide on a soln. of sodium tellurate. J. J. Berzelius obtained pale yellow, four-sided prisms of **potassium sulphotellurite,** K_6TeS_5, by an analogous process. The salt readily fuses to a black liquid which, on cooling, forms a yellowish-brown solid, soluble in water. The salt blackens in moist air, and dil. aq. soln. are also quickly decomposed on exposure to air. The **copper sulphotellurite,** Cu_3TeS_5, is obtained by double decomposition as a brown precipitate; similarly black **silver sulphotellurite,** Ag_6TeS_5, is produced by double decomposition. It is decomposed by heat into silver telluride, etc. By boiling calcium sulphide with tellurium disulphide and water, and evaporating the filtrate, a non-crystalline mass of **calcium sulphotellurite** is produced which decomposes rapidly on exposure to air; similarly with **strontium sulphotellurite,** which forms a pale yellow, unstable solid which is completely soluble in water; while **barium sulphotellurite** furnishes pale-yellowish four-sided prisms, fairly stable in air, which are slowly dissolved by water. By adding barium sulphotellurite to a soln. of magnesium sulphate, and evaporating the filtrate **magnesium sulphotellurite** is formed as a pale yellow crystalline mass soluble in water and alcohol, similarly with **zinc sulphotellurite,** which is at first light yellow and then turns brown; and **cadmium sulphotellurite** is formed similarly; whilst **mercurous sulphotellurite** furnishes a dark brown precipitate which decomposes with a hissing noise when heated, and giving off mercury forms yellowish-brown **mercuric sulphotellurite** which decomposes into sulphur and mercury telluride when strongly heated. When an aq. soln. of a cerous salt is treated with potassium sulphotellurite, cerium sulphotellurite is precipitated; it is brownish-yellow at first but soon becomes brownish-black. I. Pouget could not prepare *telluroantimonites* analogous to the selenoantimonites. Antimony telluride does not dissolve in a hot soln. of potassium telluride or hydrotelluride; and tellurium is itself insoluble in alkali sulphides—*vide infra.* J. J. Berzelius prepared dark brown **bismuth sulphotellurite,** by a similar process, a brown precipitate of **stannous sulphotellurite,** and a dark brown precipitate of **stannic sulphotellurite.** According to A. Ditte, tellurium dissolves in boiling soln. of the alkali sulphides, but tellurium is deposited in crystals as the soln. cools. It forms no *alkali tellurosulphostannates* analogous to the seleno-sulphostannates. J. J. Berzelius obtained a dark brown precipitate of **lead sulphotellurite** by double decomposition. P. Saldau found that the system PbS–PbTe does not form a continuous isomorphous mixed series. J. J. Berzelius obtained a precipitate of **manganese sulphotellurite** by a similar process; likewise **ferrous sulphotellurite** appears to be formed as a black precipitate; **ferric sulphotellurite** in brown flakes; **cobalt sulphotellurite,** as a black precipitate and likewise also with **nickel sulphotellurite.** A dark yellow soln. of **platinum sulphotellurite** was produced by the action of potassium sulphotellurite on a soln. of platinum tetrachloride; in a few days, it deposits the sulpho-salt in dark blue flakes which turn black when dried.

J. B. Hannay[2] reported a supposed **arsenic sulphotellurite,** $As_2S_3.2TeS_2$, which was called **arsenotellurite.** It was said to occur in small brownish needles on arsenical iron pyrites. The complex mineral from Nagyag, called *Blättertellur*—foliated tellurium—was named **nagyagite** by W. Haidinger[3]—*vide supra.* It is the *aurum galena* of G. A. Scopoli; the *or gris lamelleux* of I. Eques a Born; the *elasmose* of F. S. Beudant; the *Nagyakererz* of A. G. Werner; the *Blättererz* of D. L. G. Karsten; and the *blatterine* of J. J. N. Huot. Analyses were reported by P. Berthier, R. Brandes, F. Folbert, W. Hanko, S. J. Kappel, M. H. Klaproth, G. A. Kenngott, C. F. Plattner, E. Priwoznik, P. Schönbein, W. Muthmann and E. C. Schröder, E. S. Simpson, and P. Sipöcz. The results show that although the mineral is a **lead gold sulphotellurantimonite,** no definite formula can be assigned to the mineral. The composition ranges from $Pb_{10}(Au,Ag)_2Sb_2Te_6S_{15}$ to $Pb_{17}(Au,Ag)_4Sb_4Te_{10}S_{18}$. The formula was discussed by A. K. Boldireff. The occurrence of nagyagite at Nagyag and Offenbanyer, Transylvania, was discussed by M. H. Klaproth, J. F. L. Hausmann, B. von Inkey, G. vom Rath, A. Schrauf, H. Höfer, F. R. von Hauer and G. Stache, F. Beyschlag, V. R. von Zepharovich, and E. von Fellenberg and B. von Cotta; in Hungary, by F. von Richthofen, J. D. Dana, and A. des Cloizeaux. The *silberphyllinglanz* of A. Breithaupt, named *nobilite* by M. Adam, occurs at Deutsch-Pilsen, Hungary. A. Breithaupt called an auriferous variety of nagyagite, *edler Molybdänglanz.* The occurrence of nagyagite in North Carolina was described by F. A. Genth, and J. D. Dana; in Virginia, by G. A. Kenngott; in New Zealand, by J. Park; and in West Australia, by E. S. Simpson. According to J. C. L. Schröder van der Kolk, the streak of dark lead-grey mineral has a brownish tinge. The mineral occurs in granular or foliated masses, or in thin, flexible plates which, according to A. Schrauf, belong to the rhombic system, having the axial ratios $a:b:c=0{\cdot}2897:1:0{\cdot}2761$. The (010)-faces may be striated; and the (010)-cleavage perfect. The crystals were described by W. Phillips, W. H. Miller, J. D. Dana, and L. Fletcher; J. R. Blum described pseudomorphs of copper pyrites after nagyagite. The sp. gr. given by L. Sipöcz is 7·4613; by W. Hanko, 7·347; and by W. Petz, 7·22. The hardness is over 1·0. J. Joly found nagyagite gives a sublimate of tellurium monoxide between 440° and 525°; and of the dioxide at 610°. A. de Gramont described the spark spectrum; F. Beijerinck, and R. G. Harvey said that it is a good electrical conductor; and E. T. Wherry, that it is a poor radio-detector. For **bismuth sulphoditellurite,** Bi_2STe_2, *vide supra,* tetradymite.

A. Oppenheim reported that salts of the hypothetical *sulphotelluric acid,* H_2TeS_4, can be prepared as **sulphotellurates;** thus, by passing hydrogen sulphide into a soln. of sodium tellurate, and adding sodium hydroxide, the precipitated tellurium trisulphide passes into soln., and the liquid after saturating it again with hydrogen sulphide, furnishes sulphur-yellow, needle-like crystals of **sodium sulphotellurate,** Na_2TeS_4. The formation of the salt is represented by the equation: $2Na_2TeO_4+7H_2S=Te+3S+Na_2TeS_4+2NaOH+6H_2O$; similarly with **potassium sulphotellurate,** K_2TeS_4. The aq. soln. can be boiled without decomposition. L. Staudenmaier said that it is probable that in alkaline soln., the telluric acid is reduced by hydrogen sulphide so that the alleged sulphotellurates are really sulphotellurites. A. Gutbier and F. Flury could not prepare alkali sulphotellurates, and stated that with alkali tellurates, hydrogen sulphide gives no product approximating $Na_2TeS_3.2H_2S$.

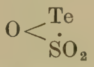
§ 15. Tellurium Oxysulphides and Sulphates

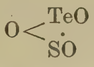
R. Weber,[1] and E. Divers and M. Shimose found that when sulphur trioxide reacts with tellurium, **tellurium sulphotrioxide,** $TeSO_3$, is formed. The two substances may remain in contact for a short time without reaction, and for a longer time if the mixture is cold. There is an evolution of heat, and the reaction is completed a few minutes after it has started. The excess of sulphur trioxide remains colourless; the sulphotrioxide is a bulky, deep red solid. After the sulphotrioxide had been digested in the liquid trioxide at 30°–40° for some time, the liquid was drained off and the adherent trioxide was removed by heating it to 35° in vacuo, and the trioxide absorbed by means of borax—potassium hydroxide as absorbent acts too violently. E. Divers and M. Shimose made the sulphotrioxide by the action of hydrogen telluride on a soln. of tellurium dioxide in conc. sulphuric acid: $2H_2Te+TeO_2+3H_2SO_4=3TeSO_3+5H_2O$; by the action of conc. sulphuric acid on tellurium monoxide: $2TeO+3H_2SO_4=TeSO_3+Te(SO_4)_2+3H_2O$. The red colour of a soln. of tellurium in fuming or conc. sulphuric acid—noticed by M. H. Klaproth, A. Hilger, A. C. Schultz-Sellack, F. J. Müller von Reichenstein, H. G. Magnus, F. von Kobell, H. Rose, J. J. Berzelius, and N. W. Fischer—was attributed by R. Weber, and E. Divers and M. Shimose to the presence of tellurium sulphotrioxide, and W. Prandtl and P. Borinsky obtained the sulphotrioxide by the action of chlorosulphonic acid on tellurium. N. W. Fischer said that the red colour appears when one part of tellurium is present in 2000 parts of acid; no sulphur dioxide is evolved as the red coloration is produced. If the red soln. is heated, the red colour disappears, tellurium sulphate is formed, and sulphur dioxide is given off. E. Moles studied the f.p. and conductivity of a soln. of tellurium in sulphuric acid, and obtained abnormal values for the mol. wt. R. Auerbach found that tellurium dissolves in pyrosulphuric acid as single atoms; and on coagulation by dilution with water, the colour changes from red, through violet, to blue as the metal is precipitated—*cf.* selenium oxysulphate.

According to R. Weber, and E. Divers and M. Shimose, at ordinary temp. tellurium sulphotrioxide is an amorphous solid, which softens without melting at about 30°. It is of a beautiful red colour, and transparent in very thin layers. It is finely vesiculated in consequence of the vaporization within its substance of the excess of sulphur trioxide at first mixed with it. R. Weber said that it is very unstable, decomposing even in sealed tubes at ordinary temp. yielding sulphur dioxide, but E. Divers and M. Shimose observed it to be quite stable at ordinary temp. in the closed tube when pure, neither changing colour nor evolving sulphur dioxide. During its preparation and purification, also, no sulphur dioxide was produced, when the sulphur trioxide was quite anhydrous. The sulphotrioxide does, indeed, sometimes slowly decompose when left in the crude state, its red colour assuming a brown shade, and then, too, sulphur dioxide is formed. E. Divers and M. Shimose also observed that when red tellurium sulphotrioxide is heated sufficiently, its colour changes to a bright fawn-brown. Prolonged heating in a vacuum even at 35° effects this change, but so very slowly that no change can be perceived, even after the lapse of an hour. At higher temp. the transformation is more rapid, and at 90°, almost instantaneous. No gas is evolved, and nothing but the striking change of colour is observable. The vesicular condition remains just as it was, even to the iridescence of the superficial vesicles. Heated to 130°, it softens and shrinks, as the vesicular structure collapses. Its brown colour is now of a deeper shade, owing to the absence of the vesicles. Heated to 180°, it again changes colour, and again becomes vesiculated, this time from evolution of sulphur dioxide. The mass eventually becomes black and solid on further heating, and now consists of the tellurium monoxide, the decomposition being almost complete at about 230°. The earlier effects of heating the red sulphotrioxide under atm. press. do not appear to differ essentially from those of heating in vacuo. The brown sulphotrioxide remains unaffected when digested with liquid sulphur trioxide, but like the red sulphotrioxide it dissolves readily in sulphuric acid, without evolution of sulphur dioxide, and yields the usual deep amethyst-red soln. In its behaviour with water, no difference from the red sulphotrioxide has been observed, if we except a somewhat more violent action in the case of the red, perhaps due to the presence of a little sulphur trioxide in the preparation so tested. If water be passed into the red soln. of tellurium in sulphuric acid, the tellurium is all precipitated; and tellurium sulphotrioxide is decomposed by water $TeSO_3+H_2O=Te+H_2SO_4$, but some tellurium monoxide is formed (*q.v.*): $TeSO_3+H_2O=H_2SO_3+TeO$, followed by $2TeO+H_2O=Te+H_2TeO_3$; or collectively $2TeSO_3+3H_2O=Te+H_2TeO_3+2H_2SO_3$. These equations, said E. Divers and M. Shimose, "do not make at all clear the production of excess of tellurium, and that of the sulphuric acid remains inexplicable, since sulphurous acid has no reducing action upon tellurous acid either alone or in the presence of sulphuric acid, hydrochloric acid being required. Nor is the constitution clear. If the sulphoxide is a sulphite, it is strange that it should dissolve in sulphuric acid without giving off sulphurous acid. Further, if it is a sulphite, it should be in the same series of tellurium compounds as tellurium monoxide, and there should be a corresponding hypotellurous sulphate, SO_4Te, formed from tellurium monoxide and sulphuric acid, which is not the case. They suggested the formulæ:



$$O{<}\genfrac{}{}{0pt}{}{Te}{SO_2}$$

Red sulphotrioxide.



$$O{<}\genfrac{}{}{0pt}{}{TeO}{SO}$$

Brown sulphotrioxide.

which represent the red modification as a sulphonate of tellurium in the unstable condition of bivalency, and the brown modification as a better balanced combination of oxides of the two elements, in which both are quadrivalent, and the combination, therefore, more stable under rise of temp. than the red modification, and yet a combination out of which the tellurium cannot be expected to separate from the sulphur without reduction at the same time to a state of lower valency." R. Auerbach said that tellurium dissolves as Te-mols. in pyrosulphuric acid. W. Prandtl and P. Borinsky, by analogy with their hypothesis for sulphur sesquioxide, represented the constitution of tellurium sulphotrioxide:

Vide the action of tellurium on selenic acid. According to C. A. Cameron and J. Macallan, coloured compounds produced by the action of sulphur, selenium, and tellurium on selenic acid have been produced by the action of these elements on sulphuric acid or anhydride to form the compounds SSO_3, $SeSO_3$, and $TeSO_3$. Owing to their similarity in the modes of formation with those formed by selenic acid, it is assumed that the resulting *selenotrioxides* are analogous to the *sulphotrioxides* in which selenium and sulphur are mutually replaceable. The two series of compounds are:

	Sulphotrioxides.	Selenotrioxides.
Blue	SSO_3	$SSeO_3$
Green	$SeSO_3$	$SeSeO_3$
Red	$TeSO_3$	$TeSeO_3$

The colour of the above compounds appears to be almost entirely due to the element which is added on to the anhydride; the sulphur or selenium in the residual portion of the mol. has scarcely any effect upon the colour.

J. J. Berzelius[2] evaporated a soln. of tellurium in conc. sulphuric acid, and obtained what he regarded as the normal sulphate; but D. Klein and J. Morel showed that the product is probably a basic salt, **telluryl oxysulphate,** $2TeO_2.SO_3$; or $Te_2O_3(SO_4)$; or $O=(TeO)_2=SO_4$. B. Brauner obtained this product by boiling tellurium dioxide with sulphuric acid (1 : 1), and cooling the soln. D. Klein and J. Morel, P. Köthner, and R. Metzner used a more dil. acid, and evaporated the soln. for crystallization. B. Brauner said that if less than 50 per cent. sulphuric acid is used, tellurium dioxide separates from the soln. J. J. Berzelius, A. Gutbier, and E. Divers and M. Shimose obtained the salt from a soln. of tellurium in hot sulphuric acid. The salt furnishes rhombic prismatic crystals, which, according to K. Vrba, have the axial ratios $a:b:c=0·5265:1:0·7860$; the (001)-cleavage is complete; complex twinning occurs about the (110)-plane. The crystals produced by the slow cooling of the sulphuric acid soln. are colourless six-sided prisms; and those obtained by rapid cooling are microscopic, six-sided plates. The sp. gr. of the tabular crystals is 4·605, and that of the prismatic crystals 4·7. R. Metzner found that the crystals are non-hygroscopic, and stable. No decomposition occurs at 440°, but at 500°, a little decomposition occurs. Hence it is easy to separate adherent sulphuric acid from the crystals, by heating them in vacuo. J. J. Berzelius said that the salt melts when heated, and at a higher temp. gives off sulphur trioxide leaving a residue of tellurium dioxide; cold water acts slowly on the salt, and hot water transforms it completely into tellurium dioxide and sulphuric acid. It dissolves in warm hydrochloric and nitric acids, and separates on cooling the hot, sat. soln. R. Metzner utilized the properties of this sulphate for the separation of selenium and tellurium. F. Ephraim prepared **tellurium hexamminosulphate,** $TeSO_4.6NH_3$.

R. Metzner prepared **ammonium sulphatotellurite,** $(NH_4)HSO_4.2TeO_2.SO_3.2H_2O$, by adding ammonium sulphate to a soln. of telluryloxysulphate in hot, dil. sulphuric acid; on cooling, acicular crystals separate out. He also prepared **potassium sulphatotellurite,** $KHSO_4.2TeO_2.SO_3.2H_2O$, in a similar manner. G. Pellini observed that **rubidium hydrosulphatohydrotellurate,** $Rb(HSO_4)(HTeO_4)$, may be formed—*vide supra,* hydrotellurates. F. Förster and co-workers observed no sign of the possible formation of *tellurothiosulphuric acid,* or tellurodithionic acid corresponding with the corresponding selenium compounds (*q.v.*). W. Prandtl and P. Borinsky obtained **tellurium hexoxydisulphotetrachloride,** $TeCl_4.2SO_3$, by the action of pyrosulphuryl chloride on tellurium; or of sulphur trioxide on tellurium tetrachloride. The complex melts in vacuo at 85°; and at 120° in vacuo it furnishes **tellurium trioxysulphotetrachloride,** $TeCl_4.SO_3$. It was also found that sulphur trioxide reacts with tellurium tetrabromide and **tellurium heptoxydisulphodibromide,** $TeOBr_2.2SO_3$, is formed.

§ 16. Tellurium Nitrates

M. H. Klaproth,[1] and J. J. Berzelius found that tellurium is readily dissolved by nitric acid forming a colourless soln. D. Klein and J. Morel's observations on this subject have been discussed in connection with tellurium itself. With an acid of sp. gr. 1·15, the evaporation of the soln. at about 50° furnishes, according to J. F. Norris and co-workers, and P. Köthner, **telluryl oxyhydroxynitrate,** $Te_2O_3(OH)(NO_3)$, that is, $HO{-}TeO{-}O{-}TeO{-}NO_3$. P. Köthner said that the formula $4TeO_2.N_2O_5.1{\cdot}5H_2O$ is not correct. According to P. Köthner, the salt is best prepared by dissolving tellurium in a slight excess of nitric acid; and evaporating the liquid so as to obtain crystals from the hot soln. The crystals are washed with warm nitric acid of sp. gr. 1·255, and then with colder acid; and then with acid at 5°, then with a 3 : 1-mixture of cold nitric acid and absolute alcohol; then gradually raising the proportion of alcohol until finally alcohol alone is used to remove the last trace of nitric acid. The crystals are then dried in vacuo over phosphorus pentoxide. P. Köthner obtained the crystals as rhombic prisms from hot soln. J. F. Norris and co-workers said that the crystals are not hygroscopic, and do not lose their lustre when exposed to air, but in moist air, P. Köthner found that tellurous and nitric acids are formed. The salt is not changed when kept in vacuo over calcium chloride. J. F. Norris and co-workers said that the nitrate suffers no loss in weight from 110° to 170°, but at 190° the crystals begin to lose nitrogen oxide; and tellurium dioxide is formed at 300°. According to D. Klein and J. Morel, the basic nitrate is slowly decomposed by cold water, nitric acid and a small proportion of tellurium dioxide is dissolved, while rectangular plates of tellurium dioxide remain. At a higher temp., decomposition is almost instantaneous; the soln. becomes strongly acid, and the greater part of the tellurium dioxide remains undissolved in the form of microscopic octahedra. These facts explain the commonly-accepted statement that tellurium dioxide is slightly soluble in water, but does not redden blue litmus. The basic nitrate does not act on moistened litmus in the cold until after several hours, and when decomposition takes place the soln. of a small quantity of tellurium dioxide is due to the presence of the free nitric acid. Basic tellurium nitrate dissolves in nitric acid and crystallizes readily when the soln. is concentrated and cooled. It seems to be much more soluble in the dil. than in the conc. acid. Soln. in nitric acid of sp. gr. 1·1–1·4 are stable at all temp. and soln. in acid of sp. gr. about 1·35, are not decomposed on addition of 100 vols. of water. On the other hand, soln. in nitric acid of sp. gr. 1·1 are decomposed by water with precipitation of tellurium dioxide, decomposition being more rapid the greater the proportion of water. The limit of decomposition appears to be reached when the soln. is mixed with 5 vols. of water; under these conditions, the precipitation of tellurium dioxide is very slow, and with a smaller proportion of water no decomposition takes place. The tellurium dioxide deposited when the nitric acid soln. are diluted, does not crystallize in octahedra, but in some perfectly distinct form.

A. Rosenheim and G. Jander found that soln. containing telluric acid and potassium nitrate deposit large crystals of **potassium dinitratotellurate,** $2KNO_3.H_6TeO_6.2H_2O$; and they can be recrystallized from dil. soln. of potassium nitrate without decomposition. Similarly, with soln. of silver nitrate, crystals of **silver nitratotellurate,** $AgNO_3.H_6TeO_6$, were formed. They attributed the formation of these complexes to the weak acid nature of telluric acid. A. Oppenheim also obtained silver nitratotellurate as a precipitate by adding silver nitrate to a soln. of telluric acid ; similarly with **mercurous nitratotellurate,** and with **lead nitratotellurate.**

§ 17. Tellurium Phosphates

J. J. Berzelius,[1] and H. Rose observed that when a soln. of sodium phosphate is added to a neutral or feebly acid soln. of tellurous acid a white precipitate is formed ; and D. Klein found that the spontaneous evaporation of a soln. of tellurous acid in conc. phosphoric acid furnishes pulverulent *tellurium phosphate* which cannot be washed with water because it is resolved by that liquid into tellurium dioxide and phosphoric acid. The product contains a variable proportion of phosphoric acid. F. Ephraim and E. Majler were unable to prepare an ammonium phosphotellurate analogous to the phosphoselenates. According to R. F. Weinland and H. Prause, telluric acid forms compounds with phosphates analogous with those obtained with the arsenates, thus, **ammonium diphosphatotellurate,** $2(NH_4)_2O.P_2O_5.TeO_3.4H_2O$, that is, $\{(NH_4O)_2{=}PO\}_2TeO_2$, was obtained by evaporating a soln. of 2 mols of phosphoric acid, a mol of orthotelluric acid, and 4 mols of ammonia. The four-sided plates belong to the triclinic system, and have the axial ratios $a:b:c=0\cdot7337:1:0\cdot7698$, and $\alpha=90° \, 28'$, $\beta=96° \, 42'$, and $\gamma=91° \, 34'$. The salt is easily soluble in water, and the soln. has an alkaline reaction ; it can be recrystallized from water ; but it ought not to be warmed very much or ammonia will be given off. If the three components just indicated be in proportions between 2 : 1 : 2·5 and 4 : 1 : 6, **ammonium triphosphatotellurate,** $4(NH_4)_2O.3P_2O_5.2TeO_3.11H_2O$, or $\{NH_4O\text{–}PO(OH)\}_2TeO_2 : TeO(OH).PO(ONH_4)_2$, is produced in monoclinic prisms or plates with the axial ratios $a:b:c=0\cdot8097:1:0\cdot6347$, and $\beta=116° \, 25'$, with twinning about the (001)-plane. The crystals react acid ; they can be recrystallized from water ; and they do not effloresce over sulphuric acid. By evaporating slowly over sulphuric acid a soln. of 2 mols of phosphoric acid, one mol of orthotelluric acid, and 2 mols of sodium hydroxide, six-sided, bipyramidal crystals of **sodium phosphatotellurate,** $2Na_2O.P_2O_5.2TeO_3.9H_2O$, or $(NaO)_2PO.O.TeO_2(OH)$, are formed. The salt cannot be recrystallized from water without decomposition. The hexagonal crystals have the axial ratio $a:c=1:1\cdot3646$; they do not effloresce over sulphuric acid ; they are sparingly soluble in cold water ; the aq. soln. is slightly alkaline towards litmus. R. F. Weinland and H. Prause prepared **potassium hydrodiphosphatotellurate,** $1\frac{1}{2}K_2O.P_2O_5.TeO_3.17\frac{1}{2}H_2O$, or

$$\begin{matrix}KO\\KO\end{matrix}{>}PO\text{–}O\text{–}TeO_2\text{–}O\text{–}PO{<}\begin{matrix}OK\\OK\end{matrix}\cdot 17H_2O$$

by the evaporation in vacuo over conc. sulphuric acid or at a temp. below 40°, of a soln. of theoretical proportions of the component salts. The acicular or prismatic crystals of the *heptadecahydrate* effloresce at ordinary temp., but are stable at 4° or 5°. The salt is soluble in water, and the aq. soln. reacts acidic. The salt loses all its water at 200° ; and over sulphuric acid, about three-fourths of the water is given off forming the *tetrahydrate*, $(KO)_2PO.O.TeO_2O.PO(OH)OK.6H_2O$. The same salt is produced as in the case of the heptadecahydrate using a conc. soln. of phosphoric acid, or a soln. of 4 mols of phosphoric acid, one mol of orthotelluric acid, and 5 mols of potassium hydroxide. The salt forms radiating aggregates of rhombic crystals which do not effloresce in the desiccator, and lose no water at 100°. The corresponding **rubidium hydrophosphatotellurate,** $(RbO)_2PO.O.TeO_2.O.PO(OH)ORb.4H_2O$, was obtained from a soln. of 4 mols of phosphoric acid, one mol of orthotelluric acid, and 6 mols of rubidium hydroxide.

For tellurium phosphotridecachloride, $2TeCl_4.PCl_5$, *vide supra.*

CHAPTER LX

CHROMIUM

§ 1. The History and Occurrence of Chromium

In 1766, J. G. Lehmann[1] described *nova minera plumbi specie crystallina rubra* which he had obtained from Ekateribourg, Siberia, but for the next thirty years, the composition of the mineral was more or less conjectural. P. S. Pallas, indeed, said that it contained lead, sulphur, and arsenic. J. G. Wallerius called it *minera plumbi rubra ;* A. G. Werner, *rothes Bleierz ;* and L. C. H. Macquart, *plomb rouge de Sibérie—vide infra,* crocoite. J. J. Bindheim supposed the mineral to be a compound of molybdic acid, nickel, cobalt, iron, and copper. In 1794, L. N. Vauquelin in co-operation with L. C. H. Macquart, reported that it contained lead oxide, iron, alumina, and a large proportion—38 per cent.—of oxygen—*oxyde de plomb suroxygéne ;* but in 1797, L. N. Vauquelin, in his *Mémoire sur une nouvelle substance métallique, contenue dans le plomb rouge de Sibérie, et qu'on propose d'appeler chrome,* showed that the contained lead was united to a peculiar acid which was shown to be the oxide of a new metal to which he applied the name *chrom*—from χρῶμα, colour—*parce que ses combinaisons sont toutes plus ou moins colorées.* L. N. Vauquelin said :

> I observed that when the powdered mineral is boiled with a soln. of two parts of potassium carbonate, the lead combines with the carbonic acid, and the alkali, with the peculiar acid, to form a yellow soln. which furnishes a crystalline salt (potassium chromate) of the same colour. The mineral is decomposed by mineral acids, and when the soln. is evaporated it furnishes a lead salt of the mineral acid, and *l'acide du plomb rouge* (chromic acid) in long prisms the colour of the ruby. When the compound of *l'acide du plomb rouge* with potash is treated with mercury nitrate, it gives a red precipitate, the colour of cinnabar ; with lead nitrate, an orange-yellow precipitate ; with copper nitrate, a maroon-red, etc. *L'acide du plomb rouge,* free or in combination, dissolves in fused borax, microcosmic salt, or glass to which it communicates a beautiful emerald green colour.

L. N. Vauquelin isolated a pale-grey metal by heating a mixture of the chromic acid and carbon in a graphite crucible. About the same time as L. N. Vauquelin, M. H. Klaproth, in 1797, also demonstrated the presence of a new element in the red Siberian ore, but in a letter to *Crell's Annalen* he stated that L. N. Vauquelin had anticipated his discovery. M. H. Klaproth had dissolved the mineral in hydrochloric acid, and after crystallizing out the lead chloride, he saturated the liquid with sodium carbonate, and obtained the *Metallkalk.* He also noted the characteristic colour which it imparted to fused borax, and fused microcosmic salt. The results were confirmed by J. F. Gmelin, A. Mussin-Puschkin, S. M. Godon de St. Menin, and J. B. Richter. F. Brandenburg tried to show that the chromic acid of L. N. Vauquelin is really a compound of chromic oxide and one of the mineral acids, but K. F. W. Meissner, and J. W. Döbereiner proved this hypothesis to be untenable.

Chromium is widely diffused, but does not occur in the free state. F. W. Clarke[2] estimated that the igneous rocks of the earth's lithosphere contain 0·052 per cent. Cr_2O_3, 0·045 per cent. Cl, and 0·051 per cent. BaO. F. W. Clarke gave 0·37 per cent. Cr ; F. W. Clarke and H. S. Washington, 0·68 per cent. ; H. S. Washington gave 0·20 per cent.; G. Berg, 0·033 per cent.; and J. H. L. Vogt, 0·01 per cent. W. Vernadsky gave 0·0033 for the percentage amount, and 0·01 for the atomic proportion. F. W. Clarke and H. S. Washington estimated that the earth's 10-mile crust, the hydrosphere and atm. contained 0·062 per cent. Cr; and the earth's 25-mile crust, the hydrosphere and atm., 0·65 per cent. of Cr. W. and J. Noddack and O. Berg gave for the absolute abundance of the elements in the earth: Cr, 3×10^{-5}; and Fe, 10^{-2}; whilst A. von Antropoff obtained for the atomic percentages, 0·29 in stellar atmospheres; 0·021 in the earth's crust; 0·05 in the whole earth; and 0·29 in silicate meteorites. The subject was also discussed by V. M. Goldschmidt, G. Tamman, R. A. Sonder, P. Niggli, E. Herlinger, O. Hahn, J. Joly, and H. S. Washington. P. Pondal said that the proportion of chromium in basic rocks is greater than it is in acidic rocks where the proportion is very low or zero; he found 0·32 to 0·002 per cent. of Cr_2O_3 in 15 samples of Galician magmas.

Chromium occurs in minerals of extra-terrestrial origin. A. Laugier[3] found it in a meteorite from Vago. According to L. W. Gilbert, J. Lowitz had previously found chromium in a meteorite from Jigalowka, but the analysis was not published. Numerous analysis of other meteorites have been reported by E. Cohen, and others. J. N. Lockyer studied the spectra of meteorites. The general results show that chromium is a constant constituent of these meteorites. The amounts vary from 0·003 to 4·41 per cent. In most cases it is present as chromite; sometimes in the chondrite, olivine, pyroxene, pictotite, and *daubréeite*, $FeCr_2S_4$. H. A. Rowland,[4] T. Dunham and C. E. Moore, S. A. Mitchell, P. W. Merrill, H. Deslandres, G. Kirchhoff, J. N. Lockyer, and F. McClean, reported that the spectral lines of chromium appear in the solar or in stellar spectra. H. Deslandres also found chromium lines in the ultra-violet spectrum of the corona.

The principal mineral for the supply of chromium is *chromite*. It has a variety of names: *chrome ore, chrome-ironstone*, or *chrome iron ore*, $FeO.Cr_2O_3$, in which the iron and chromium are more or less replaced by magnesium and aluminium. Iron ore with up to about 3 per cent. of chromium is called *chromiferous iron ore*. The origin of the chromite deposits has been discussed by M. E. Glasser,[5] L. W. Fisher, E. Sampson, F. Ryba, C. S. Hitchin, J. S. Diller, P. A. Wagner, E. A. V. Zeally, J. H. L. Vogt, W. N. Benson, A. C. Gill, C. S. Ross, and J. T. Singewald. E. Sampson believed that although chromite may crystallize at a late stage as a magmatic mineral, a large proportion passes into a residual soln., or into a highly aq. soln. capable of considerable migration. The following analyses, Table I, were quoted by W. G. Rumbold:[6]

TABLE I.—ANALYSES OF CHROMITE ORES.

Locality.	Cr_2O_3.	FeO.	MgO.	Al_2O_3.	SiO_2.
Baluchestan . . .	57·0	13·6	16·6	9·8	1·2
Selukwe, Rhodesia . .	46·5	15·7	11·7	15·5	8·0
Canada	46·0	22·5	4·9	8·9	7·7
Urals, Russia . . .	55·8	21·6	13·9	3·3	5·4
Orsova, Hungary . . .	39·0	16·1	17·2	17·5	8·0
Asia Minor	60·1	15·7	16·4	6·3	1·1
California	43·7	14·0	16·5	16·0	8·0
North Carolina . . .	57·8	25·7	5·3	7·8	2·8
New Caledonia . . .	54·5	17·7	8·0	11·1	3·1

The commercial value of the ore is based on the proportion of contained chromic oxide. The ore may be sold per ton; or per unit of contained chromic oxide over, say, a 50 per cent. standard. Prior to the Great War, Rhodesia and New Caledonia were the chief producing countries; during the years of the war, and with the lack of facilities for ocean freights, there were marked increases in output from

United States, India, and Canada. The geographical distribution of chrome ore is illustrated in a general way by the map, Fig. 1.

Europe.—In the **United Kingdom,**[7] deposits are associated with the serpentine near Loch Tay, and on the Island of Unst, Shetland. In **Austria,**[8] the ore has been worked in the Gulse Valley, and in Styria; in **Hungary**, at Orsova,[9] there are low grade ores at Ogradina, Dubova, Placishevitsa, Tsoritza, and Eibenthal; and in **Serbia,**[10] near Cacak. In **Germany,**[11] there is a large deposit of chromite on the south side of Mount Zobten, Lower Silesia; the exploitation of the chromite near Frankenstein, Lower Silesia, has not been a commercial success. In **Italy,**[12] at Ziona. **Greece**[13] has been a steady producer of chromite for many years; there are important deposits at Volo, and Pharsala; there are deposits in the provinces of Salonika, Lokris, and Boitio; and on the islands of Euboea, and Skyros. E. Nowack,[14] and D. A. Wray described the deposits in Macedonia and **Albania.** In **Turkey,**[15] there are deposits of chrome iron ore. In **Norway,**[16] there are deposits at Trondhjem, and Röraas; those in **Sweden** were discussed by F. R. Tegengren.[17] In **Portugal,**[18] there is a deposit near Braganca; and in **Spain,**[19] near Huelva. **Russia**[20] is rich in chromite ore, and was formerly a large producer. Chrome ore is found associated with the soapstones and serpentines of the Ural Mountains—*e.g.* on the banks of the Kamenka and Fopkaja. Masses of chromite occur at Orenburg. In **Jugoslavia** chrome ore occurs at Ridjerstica in Serbia; and in the valleys of Dubostica, Tribia, and Krivaia in Bosnia.[21] Chromite also occurs at Raduscha, and the provinces of Kossovo and Monastir. P. Lepez,[22] E. Nowack, and D. A. Wray described the deposits of north-west **Macedonia.**

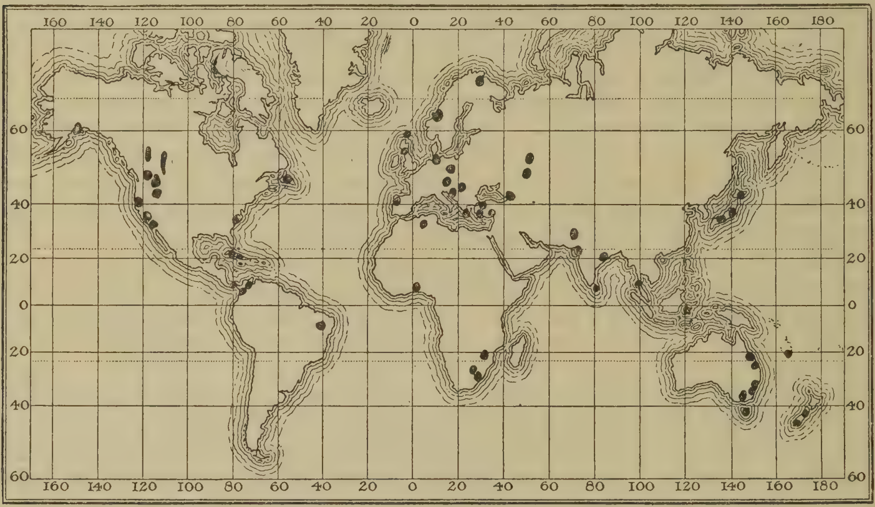

FIG. 1.—Geographical Distribution of Chrome Ores.

Asia.—In Northern **Borneo**, there are deposits on the Malliwalli Island, and chromite sands on the Marasinsing Beach. In the Islands of **Celebes,**[23] also, there are chromite sands. In **Ceylon**, alluvial chromite occurs in the Bambarabotuwa district. In **India,**[24] chromite occurs in the periodotite rocks near Salem, Madras, and also in the Andaman. There is a deposit near Khanogia, Pischin, and in the districts of Mysore, Hassan, and Shimoga of the State of Mysore. There are also deposits of chromite in Bihar and Orissa of the Singhbhum district near Retnagiri, Bombay Presidency; and in the Hindubagh district of Baluchistan. In **Asia Minor,**[25] deposits were discovered in 1848; and from about 1860 to 1903, that country supplied about half the world's output. There are several mines near Brusa. There are also deposits in Smyrna, Adana, Konia, and Anatolia. In the **Netherlands East Indies,** there is a deposit to the north of Malili, Celebes. In **Japan,**[26] there are deposits at Wakamatsu, Province of Hoki, and at Mukawa, Province of Iburi.

Africa.—In **Rhodesia,**[27] the deposits near Selukwe, Southern Rhodesia, have for some years yielded a larger output than any others. There are also deposits in Lomagundi, Victoria, and Makwiro. In **Natal**, chromite occurs at Tugela Rand, near Krantz Kop. In the **Transvaal,**[28] chromite occurs west of Pretoria; and in the districts of Lydenburg, and Rustenberg. In **Togoland,**[29] West Africa, there is a deposit between Lome and Atakpame. It also occurs in **Algeria.**

America.—In **Alaska,**[30] there are deposits of chromite on the Red Mountain, Kenai peninsula. In **Canada**,[31] chromite occurs in the neighbourhood of Coleraive, Thetford and Black Lake in the Province of Quebec. The Mastadon claim, British Columbia,[32] produced about 800 tons of chromite in 1918. There are deposits at Port au Hay, at Benoit Brook, and near the Bay d'Est river, Newfoundland. Many deposits of chromite occur in the **United States.** It occurs in thirty-two counties of the State of California: [33] Alameda, Amador, Butte, Calaveras, Colusa, Del Norte, El Dorado, Fresno, Glenn, Humboldt, Lape, Mariposa, Mendocino, Monterey, Napa, Nevada, Placer, Plumas, San Benito, San Luis Obispo, Santa Barbara, Santa Clara, Shasta, Sierra, Suskiyow, Sonoma, Stanislaus, Tehama, Trinity, Tulare, and Tuolumine; near Big Timber, and Boulder River, in Montana; at Mine Hill, and near Big Ivey Creek,[34] North Carolina; at Golconda, Oregon; [35] in Maryland; [36] in Wyoming; and on the Pacific Coast.[37] There are also chromite deposits in **Nicaragua**, in the Jalapa County, **Guatemala**; and in several parts of **Cuba.**[38] In **Brazil,**[39] there are deposits north-west of Bahia; and in **Colombia**, at Antioquia.

Australasia.—In **New Caledonia,**[40] important deposits are located amongst the mountains in the southern part of the Island. In **Australia**, there are deposits between Keppel Bay and Marlborough, Queensland; [41] near Nundl, Pueka, and Mount Lighting, New South Wales; Gippsland, Victoria; and North Dundas, and Ironstone Hill, Tasmania; and a chromiferous iron ore occurs at North Coolgardie, West Australia. In **New Zealand,**[42] chromite deposits occur at Onatea, Croiselles Harbour; in the Dun Mountain; Moke Creek, Milford Sound, in Otago; and between D'Urville Island and the gorge of Wairva River.

In 1924, the price of chrome ore ranged from 9*s.* 6*d.* to 11*s.* per unit. The world's production of chromite ore in 1913 and 1916, expressed in long tons of 2240 lb. avoir., was respectively, India, 5676, and 20,159; New Caledonia, 62,351, and 72,924; South Rhodesia, 56,593, and 79,349; Canada, —, and 24,568; Australia, 677, and 451; Bosnia, 300, and —; Greece, 6240, and 972; Japan, 1289, and 8147; and the United States, 255, and 47,034. The World's productions in these years were respectively 133,381 and 262,353. For 1922, the results were:

United Kingdom	595	Russia	1,500
South Rhodesia	83,460	Cuba	1
Union South Africa	86	Guatemala	—
Canada	685	United States	420
India	22,777	Brazil	—
Australia	529	Asia Minor	2,500
Greece	9,768	Japan	3,696
Jugoslavia	16	New Caledonia	19,063
Rumania	30	World	145,000

The minerals containing chromates include natural lead chromate, **crocoite,** or **crocoisite,** $PbCrO_4$; **phoenicochroite,** or **melanochroite,** or **phoenicite,** $3PbO.2CrO_3$; **beresowite** or **beresovite,** $6PbO.3CrO_3.CO_2$; **vauquelinite,** and **laxmannite,** $2(Pb,Cu)CrO_4.(Pb,Cu)_3(PO_4)_2$; **tarapacaite,** K_2CrO_4, mixed with sodium and potassium salts; **jossaite** contains chromates of lead and zinc; **dietzeite,** an iodate and chromate of calcium. These are also **daubreeite,** $FeCr_2S_4$; **redingtonite,** a hydrated chromic sulphate; **chromite,** $FeO.Cr_2O_3$; **magnochromite,** $(Mg,Fe)O.Cr_2O_3$; and **chromitite,** $(Fe,Al)_2O_3.2Cr_2O_3$.

C. Porlezza and A. Donati [43] observed the presence of chromium in the volcanic tufa of Fiuggi; and A. Donati, in the products of the Stromboli eruption of 1916. There is a number of silicate minerals containing chromium; in some cases the chromium is regarded as an essential constituent; in others, as a tinctorial agent—R. Klemm. The chromosilicates have been previously discussed—**6.** 40, 865. There are the calcium chrome garnet, *uwarowite;* the hydrated chromium aluminium iron silicate, *wolchonskoite;* the bright green, clayey *chrome ochre—selwynite, milochite, alexandrolite, cosmochlore* or *cosmochromite;* the chrome-augite, *omphacite* or *omphazite;* the augitic *diaclasite;* the *chromediopside;* *chromdiallage;* the *chrome-epidote* of F. Zambonini [44] or the *tawmawite* of A. W. G. Blaeck; the chromic mica *fuchsite;* the chromic muscovite, *avalite;* the chromic chlorite *kämmererite*—and the variety *rhodochrome;* as well as *chromochlorite* or *rhodophyllite*, and *pennine;* the chromic clinochlor, *ripidolite*, and *kotschubeyite;* *serpentine;* and *chromotourmaline.*

P. Groth,[45] G. Rose, and A. Schrauf found chromium in *wulfenite.* The coloration of minerals by chromium was discussed by W. Hermann,[46] K. Schlossmacher, and A. Verneuil. The coloured alumina *smaragd, sapphire,* and *syenite* are chromiferous. Some spinels are chromiferous—*e.g. chromospinel ;* and the so-called *picotite,* or *chromopicotite,* is a chromospinel ; while *alexandrite* is a chromiferous beryl. K. A. Redlich [47] described a chromiferous *talc ;* and K. Zimanyi, a chromiferous *aluminium phosphate.* Chromium occurs in the phosphate rocks of Idaho and Utah. B. Hasselberg reported traces of chromium in a specimen of *rutile* he examined spectroscopically ; E. Harbich, in *amphibole ;* and H. O'Daniel, in *pyroxene ;* A. Jorissen found chromium in the *coal* of La Haye, and the flue-dust from this fuel had 0·04 per cent. of Cr. H. Weger reported chromium in a sample of *graphite ;* F. Zambonini found chromium spectroscopically in vesbine of the crevices, etc., and in the Vesuvian lava of 1631. R. Hermann, A. Vogel, C. E. Claus, P. Collier, and G. C. Hoffmann observed chromium associated with native *platinum ;* and J. E. Stead, with *iron,* and *steel,* and basic and other slags.

Compounds of chromium do not play any known part in the economy of animals or plants ; and it has rarely been detected in animal or vegetable products. E. Demarçay [48] observed, spectroscopically, traces of chromium in the ash of Scotch fir, silver fir, vine, oak, poplar, and horn-beam ; and L. Gouldin found it in the fruit of a rose.

§ 2. The Extraction of Chromium as Chromic Oxide or Chromate

When the chromite is disseminated in disconnected patches, it is mined by open quarries generally in terraces or benches; and when large, well-defined deposits occur, as at Selukwe, Rhodesia, underground workings are practicable. Chromite is not so hard as quartz, but it is tougher, and does not break so easily. The mining is therefore assisted by blasting. Hand concentration by sorting may be used. Here the ore is separated from waste by means of a hammer; the larger pieces of ore may be broken into coarse lumps in a jaw crusher, and passed on to a revolving table or endless belt for hand-sorting. For concentrating by gravity machines, the ore is crushed moderately fine in a drop-stamping machine or in a ball mill, and then passed by water over a table concentrator whereby it is separated into (i) concentrate—consisting of chromite only; (ii) middling—containing much chromite; (iii) tailings—containing but little chromite and is sent to waste-dump; and (iv) slimes—often containing much chromite in a fine state of subdivision but not usually sufficient to deal with profitably. The middling is re-treated usually on another concentrating table. The tailings and slimes represent loss. The concentrate varies in quality, but it usually exceeds 50 per cent. chromite.[1]

Chromite can be converted into chromic oxide or chromate, by

1. *Dry processes.*—Here the powdered mineral is mixed with an alkali, and something to keep the mass open and porous while it is roasted by an oxidizing flame, say, in a reverberatory furnace, so as to form alkali chromate: $2(FeO.Cr_2O_3)+4Na_2CO_3+7O=Fe_2O_3+4Na_2CrO_4+4CO_2$. This is extracted with water and converted into dichromate by treatment with acid; the dichromate is then reduced to insoluble chromic oxide and a soluble alkali salt which is removed by lixiviation with water. The reaction was studied by A. J. Sofianopoulos, and H. A. Doerner. Technical details are indicated in the usual handbooks.[2]

If calcium chromate be treated with a soln. of potassium sulphate, the calcium chromate is converted into calcium sulphate, which is precipitated, and potassium chromate, which remains in soln. Instead of leaching the calcium chromate with a soln. of potassium sulphate, W. J. Chrystal showed that if ammonium sulphate is used, a soln. of ammonium chromate is produced, and J. J. Hood found that if the soln. of potassium salt be treated with sodium hydrosulphate, potassium sulphate crystallizes from the soln., while sodium dichromate remains in soln. According to F. M. and D. D. Spence and co-workers, if a mixture of ammonia and carbon dioxide be passed into the aq. extract of the calcium chromate, calcium carbonate is precipitated while ammonium and alkali chromate remain in soln. If the liquid be boiled, ammonia is given off, and sodium dichromate remains in soln. S. Pontius used water and carbon dioxide under press. for the leaching process. J. Brock and W. A. Rowell purified alkali chromite by treating the soln. with strontium hydroxide, and digesting the washed precipitate with a soln. of alkali sulphate or carbonate; W. J. A. Donald used calcium hydroxide or barium chloride as precipitant. A mixture of chromite with calcium carbonate and potassium carbonate was formerly much employed. Modifications of the process were described by W. J. A. Donald,[3] A. R. Lindblad, C. J. Head, S. G. Thomas, W. Gow, J. Stevenson and T. Carlile, L. I. Popoff, G. Bessa, P. Weise, P. N. Lukianoff, B. Bogitch, E. Baumgartner, W. Carpmael, Grasselli Chemical Co., N. F. Yushkevich, A. J. Sofianopoulos, R. W. Stimson, H. Specketer and G. Henschel, and C. S. Gorman. J. Booth, and S. G. Thomas heated the chromite to a high temp. before it was treated with the lime-alkali mixture. With the idea of lowering the temp. at which the chromate is formed, F. O. Ward recommended adding calcium fluoride to the mixture; and J. Massignon and E. Vatel added calcium chloride. V. A. Jacquelain recommended calcining a mixture of calcium carbonate and chromite; extracting the calcium chromate with hot water; acidifying the soln. with sulphuric acid; and precipitating the iron by the addition of a little calcium carbonate. The soln. of calcium dichromate can be treated with alkali for the alkali salt. P. Römer used alkali carbonate without the calcium carbonate; the Chemische Fabrik Billwärder digested the chromite with sodium hydroxide in an iron vessel at 500°–600° through which was passed a current of air, an oxidizing agent was also added to the mixture. H. Moissan treated ferro-chromium with fused potassium hydroxide. The Chemische Fabrik Griesheim-Elektron used a modification of the process. G. Wachtel studied the effect of the lime. He said that with lime alone there is a 90 per cent. conversion of chromic oxide used and a 30 per cent. conversion with chromite; and that about 10 per cent. of the chromic oxide acquires the property of dissolving in acids. The yield with potassium carbonate alone is only half as large as when the potassium carbonate is mixed with an equal quantity of lime. Hence, the simultaneous action of the calcium and potassium carbonate on the ore gives better results than when either is used alone. N. F. Yushkevich observed that the formation of chromate with the chromite-lime-sodium carbonate mixture is slow at 700°; at 1160°, 95 per cent. of the chromium is oxidized in thirty minutes; and at 1260° decomposition sets in. L. I. Popoff found that the speed of oxidation of rich ores is quicker than with poor ores, and the percentage yield of chromate is greater. If the chromite contains 30 to 40 per cent. Cr_2O_3, lime to the extent of 80 per cent. of the weight of the ore should be added; 90 per cent. of lime for 40 to 50 per cent. ores; and 120 to 130 per cent. of lime for over 50 per cent. ores. These quantities of lime must be increased if the temp. of oxidation exceeds 1100°. The theoretical quantity of sodium carbonate was used. H. Pincass discussed this subject. P. Römer, and N. Walberg recommended using sodium carbonate in place of the more expensive potassium carbonate. Other alkali salts have been substituted for the carbonate; thus, S. Pontius, R. A. Tilghman, and H. M. Drummond and W. J. A. Donald used alkali sulphate; J. Swindells, sodium chloride; E. P. Potter and W. H. Higgins, sodium sulphate; E. Hene, alkali hydroxide; L. N. Vauquelin, J. B. Trommsdorff, and J. F. W. Nasse, potassium nitrate; and C. S. Gorman heated a mixture of chromite, sodium chloride, and calcium hydroxide in steam at 550°–850°. H. Schwarz found that by using alkali sulphate the potassium chromate can be leached directly from the mass. Instead of using calcium carbonate, C. S. Gorman used magnesium or barium carbonate; F. F. Wolf and L. I. Popoff, iron oxide; H. A. Seegall, barium carbonate; and the Deutsche Solvay-Werke, ferric oxide. P. Monnartz made the ore into briquettes with sand, limestone, and tar; these were fed into a small blast furnace using a blast of air enriched with oxygen. The products were a ferro-chromium alloy, and a slag with 9·4 per cent. chromic oxide. Modifications of the roasting process for chromates were employed by C. Häussermann, F. Filsinger, H. A. Seegall, and J. Uppmann for recovering chromium from chromiferous residues.

W. H. Dyson and L. Aitchison[4] heated chromite mixed with a carbonaceous material to 900° in a mixture of equal vols. of hydrogen chloride and chlorine until all the iron had volatilized; the residue was then heated to 1200° in the same gases to distil off the chromium. W. Crafts reduced the ore with charcoal at 1300° to 1350°, extracted the product with conc. sulphuric acid at 100°; and the chromium may be precipitated by adding calcium chloride to convert the sulphate to chloride and precipitating as hydroxide by limestone; or the chromium can be precipitated electrolytically from the sulphate soln. According to C. Müller and co-workers, chromite is first reduced in hydrogen or in a mixture of gases containing hydrogen and the product is heated above 200° with a slight deficiency of sulphuric acid in a closed vessel lined with hard lead containing preferably 3 per cent. of Sb.

Soln. of chromates can be reduced to chromic salt by hydrogen sulphide (L. N. Vauquelin),[5] sulphur dioxide (A. F. Duflos, and J. B. Trommsdorff), alkali polysulphide (J. J. Berzelius), sulphur in a boiling soln. (G. F. C. Frick, J. L. Lassaigne, and H. Moser)—*vide infra*, chromic oxide.

2. *Wet processes.*—Chromates can be obtained from chromite or chromic oxide in the wet-way. The Chemische Fabrik Griesheim-Elektron [6] digested the powdered mineral with sulphuric acid of sp. gr. about 1·54 with an oxidizing agent like lead or manganese dioxide, potassium permanganate, etc. E. Müller and M. Soller used lead dioxide ; E. Bohlig, potassium permanganate ; E. Donath, manganese dioxide ; P. Waage and H. Kämmerer, bromine ; F. Storck and L. L. de Koninck, chloric acid ; H. Dercum, G. Feyerabend, W. Stein, and M. Balanche, bleaching powder ; and R. von Wagner used a mixture of sodium hydroxide and potassium ferricyanide. The chromium can also be extracted from chromite with acids, etc.

3. *Electrolytic processes.*—R. Lorenz [7] found that a soln. of potassium dichromate can be prepared by passing a current at 2 volts potential between an anode of ferrochrome (containing about equal quantities of chromium and iron) and a cathode of porous copper oxide, the two electrodes dipping in a soln. of potassium hydroxide contained in a beaker. Ferric oxide collects at the bottom of the beaker. The Chemische Fabrik Griesheim-Elektron obtained chromates by electrolytic oxidation with an anode of chromium, or of a chromium alloy—*e.g.* ferrochromium, an iron cathode, and a soln. of an alkali hydroxide separating the anode and cathode by a diaphragm. Sufficient alkali is added to the anode liquid to precipitate the metal alloyed with the chromium of the anode. Chromic acid and ferric sulphate can be separated by fractional crystallization. A modification of the process consists in dissolving the chromium or ferrochromium instead of using it directly as anode and then electrolyzing it, using an insoluble anode, such as lead. The cathode and anode compartments are separated by two diaphragms, and a hydroxide or a carbonate is added to the electrolyte contained in the compartment between the latter. J. Heibling used an alkali chloride or nitrite soln. as anolyte.

C. Häussermann [8] oxidized electrolytically a soln. of chromic hydroxide in soda-lye in the anode compartment, when the cathode liquid was a soln. of an indifferent salt ; D. G. Fitzgerald used an acidic soln. of chromic oxide as anode liquor, and a soln. of a zinc salt about the cathode, and on electrolysis, chromate was formed at the anode and zinc was deposited on the cathode. K. Elbs said that a current efficiency of 70 per cent. can be obtained with freshly-ignited platinum anodes of low current density. F. Regelsberger had no success in the oxidation of chromium salts in acidic soln., even with the use of a diaphragm ; but good results were obtained with alkaline soln., using lead anodes, with or without a diaphragm, with warm soln. M. de Kay Thompson studied the production of chromates by the electrolysis of sodium carbonate or hydroxide soln. with ferrochromium electrodes. E. Müller and M. Soller said that chrome alum dissolved in N-H_2SO_4 is not appreciably oxidized to chromic acid by the use of an anode of smooth platinum ; but a trace of lead in the soln. is precipitated on the anode as lead dioxide, and this brings about oxidation ; traces of chlorine also favour the oxidation. There is about one-third the oxidation with a platinized platinum anode as occurs with a lead dioxide anode. With a lead dioxide anode, the oxidation is almost quantitative in fairly conc. soln. of chrome alum, and a current density of about 0·005 amp. per sq. cm. The difference is not due to the higher potential of the lead dioxide anode, but rather depends on the lead dioxide acting catalytically as a carrier of oxygen. I. Stscherbakoff and O. Essin found that in the electrolytic production of dichromate from chromate a sudden rise in the conductivity of the electrolyte is observed when the composition corresponds to the polychromate, $Na_2Cr_4O_{12}$. In order to obtain the best yields of dichromate, electrolysis may be conducted either in normal chromate soln. at high current density or at lower current density in soln. of the above polychromate composition. According to F. Schmiedt, and A. R. y Miro, the oxidation is favoured by the presence of fluorine ions ; and M. G. Levi and F. Ageno added that with normal soln. of chromium sulphate and N-H_2SO_4, on electrolysis with platinized platinum electrodes in the presence of 0·498N-hydrofluoric acid, the yield of 78 per cent. chromic acid is comparable with that produced by lead dioxide electrodes. The Höchster Farbwerke said that in the electrochemical oxidation of a soln. of chrome alum to chromic acid, it is necessary for conc. sulphuric acid to be present, because, added F. Fichter and E. Brunner, the acid must be conc. enough to furnish sulphur tetroxide. F. Schmiedt found that the oxidation is favoured by the presence of Cy-ions (*e.g.* potassium cyanide or ferrocyanide), many oxidizing agents, compounds of phosphorus and boron, cerous nitrate, sodium molybdate or vanadate, and platinum tetrachloride. The Chemische Fabrik Buckau found that the reduction of chromate by cathodic hydrogen, in cells without diaphragms, is avoided by the use of a little acetic acid or an acetate. The electrolytic oxidation of soln. of chromium salts was also examined by M. le Blanc, F. Regelsberger, F. W. Skirrow, A. R. y Miro, L. Darmstädter, H. R. Carveth and B. E. Curry, and the Farbewerke Meister Lucius and Brüning, A. W. Burwell, I. Stscherbakoff, A. Lottermoser and K. Falk, E. Müller and E. Sauer, R. E. Pearson and E. N. Craig, M. J. Udy, and R. H. McKee and S. T. Leo.

§ 3. The Preparation of Chromium

H. N. Warren[1] reduced chromic oxide by heating in a current of *hydrogen* in a tube of compressed lime by means of the oxyhydrogen flame. W. Rohn obtained chromium by reducing chromic oxide at 1500° in a rapid current of hydrogen from which every trace of oxygen and water-vapour had been removed. J. Schilling heated ammonium chromate to whiteness in hydrogen diluted with nitrogen and obtained chromium. M. Billy passed the vapour of the chloride mixed with hydrogen over a boat containing sodium supported on a layer of sodium chloride at 400° to 420°; the hydrogen forms a layer of hydride, and this reduces the chloride, $CrCl_3+3NaH=Cr+3NaCl+3H$. M. A. Hunter and A. Jones reduced the chloride by heating it with sodium in a heavy steel bomb. As previously indicated, L. N. Vauquelin first prepared chromium metal by heating a mixture of chromic oxide and *carbon* in a graphite crucible; and J. B. Richter, and H. Moser obtained it in a similar manner. H. St. C. Deville melted the chromic oxide with not quite sufficient carbon for complete reduction at a temp. of boiling platinum in a lime crucible. According to H. Moissan, chromic oxide is reduced in a few minutes when mixed with carbon and heated in the electric arc furnace. If a large excess of carbon is employed, chromium carbide is formed. If crude chromium in a crucible lined with chromic oxide, and covered with chromic oxide is heated in the arc-furnace, chromium may be obtained free from carbon. If crude chromium is heated with an excess of chromic oxide, the resulting metal is partially oxidized or burnt. Chromium may be obtained with 1·5–1·9 per cent. of carbon by heating the crude metal mixed with lime in an electric furnace. The carbon forms calcium carbide. It is not possible to remove all the carbon by means of lime because, when the proportion of carbon has been reduced below a certain point, an inverse reaction occurs resulting in the formation of crystallized chromium calcium oxide. H. C. Greenwood found that the reduction of chromic oxide by carbon begins at 1180°–1195°, and the reduction is not quantitative. W. B. Hamilton and F. Reid used carbon. W. P. Evans's attempts to obtain chromium from chromyl fluoride, carbon and silica were unsatisfactory. V. and E. Rouff heated an intimate mixture of alkali chromate with silica and carbon to redness, and obtained alkali silicate and chromic oxide which, when intimately mixed with carbon and heated, furnishes chromium. A. Steinberg and A. Deutsch heated to 1000°–1400° a mixture of carbon and an alkaline earth chromate, and obtained chromium. H. Debray showed that if lead chromate be reduced by carbon at a red-heat, lead can be removed from the regulus by means of nitric acid—chromium remains. W. B. Balantine used calcium carbide. J. E. Loughlin heated chromic acid with a mixture of potassium cyanide and carbon. E. Viel obtained chromium from ferro-chromium or other alloys by heating in a high-temp. furnace a mixture of the alloy with an alkaline earth silicate, or with carbon and lime or alumina. E. Kunheim also heated a mixture of chromic sulphate and carbon in an electric arc-furnace, and obtained chromium. A. Binet du Jassonneix found that a mixture of *boron* and chromic oxide in a magnesia crucible heated in the electric arc-furnace furnishes chromium; if a carbon crucible is employed, the chromium always contains carbon. If the chromium boride be heated with copper in an electric furnace, and the product digested with nitric acid, chromium remains. H. Goldschmidt, L. Franck, T. Fujibayashi, and T. Goldschmidt found that chromic oxide can be reduced by the thermite process in which a mixture of chromic oxide and *aluminium* in a crucible is ignited by a fuse. E. Vigouroux, and J. W. Richards said that chromium produced by the thermite process is free from carbon. E. Vigouroux observed that a fairly pure product is formed by heating in a crucible lined with magnesia, a mixture of chromic oxide and 10–20 per cent. chromic anhydride incorporated with the necessary quantity of aluminium powder. A vigorous reaction ensues, and it is over in about a minute. The slag separates readily from the metal. The product contains 0·36–0·40 per cent. of silicon, and 0·74–0·85 per cent. of aluminium and iron. J. Olie used 20 grms. of a mixture of 50 grms. of fused and powdered potassium dichromate and 18 grms. powdered aluminium, together with 10 grms. of a mixture of 450 grms. of calcined chromic oxide and 160 grms. of powdered aluminium. T. Fujibayashi used chromic oxide (100 parts), calcium chromate (10–15 parts), and 90 per cent. of the calculated weight of powdered aluminium. An 85 to 92 per cent. yield was obtained and the resulting chromium contained 3 to 5 per cent. of aluminium. M. Yonezu used a similar process. T. Goldschmidt, M. le Blanc, and G. Döllner used *magnesium*, or a carbide, in place of aluminium in the thermite process; T. Goldschmidt, a mixture of calcium and silicon in place of aluminium; and W. Prandtl and B. Bleyer used a mixture of calcium and aluminium instead of aluminium alone; A. Burger passed the vapour of *calcium* over heated chromic oxide; and heated the product with dil. nitric acid until the acid began to boil; the product was first washed with water, then with alcohol, and finally dried at 100°. He also obtained chromium by heating a mixture of a mol of chromic oxide and 3 gram-atoms of calcium in a sealed tube. B. Neumann reduced chromic oxide with *silicon* in an electric furnace; F. M. Becket used the silicothermic process; S. Heuland reduced the oxide with *calcium silicide;* R. Byman, *ferrosilicon;* D. W. Berlin, an aluminium silicide; R. Saxon, *calcium carbide;* and L. Weiss and O. Aichel, *mischmetall.*

H. Aschermann heated a mixture of chromic and *antimonious oxide* in an electric furnace, and found that the resulting alloy loses all its antimony at a white-heat. S. Heuland melted the chromium ore in an electric furnace with a reducing agent sufficient to produce only a small amount of metal which will contain all the deleterious impurities in the ores, *e.g.*, phosphorus, carbon, or iron. The remainder of the metal is then reduced from the fused slag by addition of calcium silicide. The Metal Research Co. heated in a blast-furnace a mixture of chromic oxide, a sodium compound, and carbon so that the sodium first liberated reduces the chromic oxide to chromium. Processes for the smelting of chrome ores were described by T. R. Haglund, Aktiebolaget Ferrolegeringar, W. Bennett, W. E. S. Strong and co-workers.

F. Wöhler heated in a crucible a mixture of chromic chloride, and zinc along with a mixture of potassium and sodium chlorides; and treated the regulus with dil. nitric acid to remove the zinc. 30 grms. of chromic chloride yielded 6 to 7 grms. of chromium. The process was used by W. Prinz, E. Jäger and G. Krüss, and E. Zettnow; and M. Siewert added that the product is always contaminated with silicon derived from the crucible. F. Wöhler said that there is no advantage in using magnesium or cadmium in place of zinc; but E. Glatzel preferred magnesium. J. J. Berzelius reduced dry chromic chloride with potassium; H. St. C. Deville, sodium; E. Frémy, sodium vapour; K. Seubert and A. Schmidt, magnesium; and L. Hackspill, calcium. H. C. P. Weber heated between 700° to 1200° a mixture of chromic chloride and iron in order to produce metallic chromium and volatilize ferric chloride. If the iron is sufficiently finely divided, and a relatively low temp. is employed for reduction, chromium is obtained in a finely-divided form. If solid pieces of iron are used and the reaction takes place below the m.p. of the metals, a coating of chromium is formed on the pieces of iron. If an excess of iron is used and a sufficiently high temp. is employed, an alloy of chromium and iron is produced. Chlorides of chromium and nickel may be similarly reduced together to form alloys or mixtures with each other or with iron. Chromic oxide may be employed and converted into chloride with carbon and chlorine. The reduction process is advantageously carried out in vacuo or in an inert atm. such as nitrogen. W. P. Evans reduced the vapour of chromyl fluoride by sodium at 400°, and also by zinc near its b.p. Z. Roussin treated a feebly acidic soln. of a chromic salt with sodium amalgam, and heated the resulting chromium amalgam in hydrogen so as to volatilize the mercury. H. Moissan, J. Férée, and C. W. Vincent used a similar process. According to C. Goldschmidt, crystalline chromium is formed when a soln. of, say, chromic nitrate is kept for some days in a tin vessel.

In 1854, R. Bunsen[2] obtained chromium by the electrolysis of an aq. soln. of chromous chloride. He said:

> The density of the current—that is, the strength of the current divided by the surface of the electrode at which the electrolysis occurs—is most important, for, with increasing current density, the power of the current to overcome chemical affinity also increases. For instance, if a current of constant current strength be sent through a soln. of chromic chloride, it depends on the area of the resulting electrode whether hydrogen, chromic oxide, chromous oxide, or chromium is formed. The relative amounts of the constituents of the electrolyte through which the current passes are of no less importance. . . . The reduction to the metal occurs with boiling conc. soln. when the reducing surface receives a current of 0·067 amp. per sq. cm. . . . By using a soln. of chromous chloride, containing some chromic chloride, continuous sheets of chromium can be obtained. These are quite brittle, and the surface lying against the platinum electrode is perfectly white and of a metallic lustre. Chemically pure chromium can be obtained only in this way. It resembles iron very much in external appearance, but it is more permanent in damp air, and when heated burns to chromic oxide. Hydrochloric and sulphuric acids dissolve it slowly to chromous salts with the evolution of hydrogen; and it is scarcely attacked by nitric acid even when boiling. . . . If the current density be gradually lowered, a point is soon reached when in place of the metal, there is a copious formation of anhydrous chromous-chromic oxide. This oxide can be made only in this way, and it is purified by long boiling with aqua regia. It is a black crystalline powder, soluble in no acid, and burning in air like pyrophoric iron with a lively deflagration, to form green chromic oxide. Its composition varies between Cr_4O_5 and Cr_5O_6—*vide infra*, chromic chromate.

According to E. Müller and P. Ekwall, in the electrolysis of a soln. of chromic acid using a carbon cathode, a film of chromic chromate begins to form at a potential, measured against a normal calomel electrode, of +0·8 volt, while evolution of hydrogen begins at about —1·2 volt. With a platinum electrode, hydrogen evolution begins at about 0·4 volt, while the separation of chromium, which is contaminated with oxide, occurs at about —1·2 volt, and is preceded by the formation of the insoluble, colloidal chromic chromate film, which is first observed microscopically at —0·7 volt, and is pressed cataphoretically to the cathode. The gel is purified by dialysis, and is found to migrate to the cathode, where it is coagulated. The compound is soluble in acids and bases, and its composition corresponds to the formula $Cr_2(OH)_4CrO_4$. When present as a film, the molecules are oriented and form a diaphragm, which is impervious to CrO_4'' or $HCrO'_4$-ions, but allows $H^{\cdot}$-ions to pass. Reaction accordingly ceases until the hydrogen separation potential is exceeded when the film is broken and the reaction proceeds in accordance with the equation: $Cr_2(OH)_4CrO_4+2H_2CrO_4=2Cr^{\cdots}+3CrO_4''+4H_2O$. Deposition of chromium then occurs, and the chromic chromate film is again formed. The deposition of successive layers of this film according to the magnitude of the applied potential is shown under the microscope by differences in colour. The presence of sulphuric acid in the electrolyte modifies the film formation and increases the intervals of exposure of the electrode, whereby greater accession of chromium ions results, while contamination of the deposited metal with oxide is suppressed. M. L. V. Gayler used a one per cent. sulphuric acid soln. of chromic acid. E. Müller and J. Stscherbakoff found that in spite of its strong oxidizing action, pure chromic acid is not electrolytically reducible in aq. soln., but it becomes so on addition of SO''_4-ions. They showed that the cathode becomes coated with an invisible, non-conducting, fine-grained layer, which prevents the reduction of chromic acid. This layer becomes charged in presence of SO''_4, but this occurs only after a certain cathode potential has been attained. It is hence concluded that charging by the SO''_4-ions necessitates the electrostatic attraction of these ions by the layer of colloid. S. Takegami also studied the deposit of colloidal chromic oxide.

R. Bunsen suggested that it would be worth trying to find if allotropic forms of chromium could be produced by electrolyzing green and blue chromic salt soln. Subsequent work, however—by W. R. Whitney, etc.—has shown the hypothesis to be untenable. S. O. Cowper-Coles obtained a bright deposit of chromium from a soln. of 25 parts of chromic chloride in 75 parts of water at 88°, with a current of 0·04–0·05 amp. per sq. cm. With a cold soln., gas is evolved at both electrodes, but no metallic deposit is obtained until an excess of hydrochloric acid is added. J. Férée found that a steel-grey deposit of chromium on a platinum cathode is formed with a soln. of chromic chloride acidified with hydrochloric acid; and a silver-white deposit from a soln. containing potassium and chromic chlorides in the proportion of 1 : 3, and a current density of 0·15 amp. per sq. cm., and 8 volts. J. Voisin added that when the deposit is over 3 or 4 mm. thick, it is liable to peel off. The Wolfram-Lampen A. G. obtained chromium by the electrolysis of soln. of chromic chloride in acetone; J. Roudnick, and G. Neuendorff and F. Sauerwald, by the electrolysis of the fused silicate.

S. O. Cowper-Coles found that a soln. of 100 parts of chrome-alum in 100 parts of water with 12 parts of barium sulphate does not yield a deposit of chromium metal on electrolysis. E. Placet found that when a soln. of chrome-alum and an alkali sulphate acidified with sulphuric acid, is electrolyzed, chromium is deposited at the cathode as a hard, bluish-white, lustrous metal, which, under certain conditions, crystallizes in groups resembling the branching of firs. Other metals and alloys—bronze, copper, iron, brass, etc.—may be plated with chromium, and a surface can be obtained to resemble oxidized silver. E. Placet and J. Bonnet have a number of patents on this subject.

Various baths have been recommended and the subject of chromium plating has been discussed by M. Alkan, J. D. Alley, C. M. Alter and F. C. Mathers, R. Appel, P. Askenasy and A. Révai, E. M. Baker and E. E. Pettibone, E. M. Baker and A. M. Rente, M. Ballay,

J. F. L. Möller and E. A. G. Street obtained chromium by the electrolysis of an aq. soln. of chrome-alum and sodium sulphate at 90° with a current density of 0·4 amp. per sq. cm. R. Stahn electrolyzed soln. of chromous salts. J. Voisin also obtained no deposit of chromium with a violet soln. of chrome-alum mixed with potassium hydrosulphate, using a current density of 0·02 to 0·20 amp. per sq. cm. and 4 to 12 volts, and similarly with neutral and alkaline soln.; with a green soln. of chrome-alum and 0·18 amp. per sq. cm. a small, grey deposit of a substance soluble in hydrochloric acid was obtained. According to M. le Blanc, chromium deposits cannot be obtained in the manner described. Among other processes, the following can be used:

A sat. soln. of chromic sulphate at the temp. of the room, was used and 100 c.c. dil. to 600 c.c. with water and then sodium chloride added to saturation. A platinum foil was used as cathode. With 40 sq. cm. active cathode surface, using a current density of 0·2 amp. per sq. cm., there was obtained a quite small, black precipitate which from its behaviour appeared to be chromium. With a current density of 0·3 amp. per sq. cm. no precipitate was obtained. A precipitate did not appear when the above bath was sat. with sodium sulphate instead of sodium chloride and electrolyzed at 30° and 80° with a current of 0·2 and 0·3 amp. per sq. cm.

F. Adcock found that chromium of a high degree of purity can be obtained by the electrolysis of an aq. soln. containing 30 per cent. of purified chromic acid, and one per cent. sulphuric acid using tin or steel cathodes. In one with a steel cathode rotating 30 revs. per minute, the temp. of the bath was 20°, the voltage 5·2, and the amperage 140. The current densities at the cathode and anode were 28 amp. and 7·2 amp. per sq. dm., and the yield of chromium in 30 hrs. was 500 grms., with a current consumption of 8·3 ampère-hrs. per gram. All the samples as deposited contained hydrogen and oxygen, the former being liberated during remelting in vacuo. The cathode chromium is in a form which leaves no residue on dissolution in acid, and is converted, when heated in vacuo, into insoluble chromic oxide. This can be removed, however, by heating the solid metal in purified and dried hydrogen to 1500°–1600°. After these treatments, spectroscopic examination failed to reveal any impurities. T. Murakami studied the action of chemical reagents on the deposits.

B. Neumann and G. Glaser examined the influence of current strength, current density, conc., and temp. with different soln. of chromic salts. The diaphragm cells contained the chromium salt soln. in the cathode compartment, and a mineral acid or salt soln. in the anode chamber. The cathode was ordinary carbon, but the deposited chromium was found to adhere also to cathodes of borax, lead, or platinum; the anode, according to the soln. employed, was lead, platinum, or carbon. If the cathode soln. is not well circulated, it becomes impoverished at the cathode, and with high current densities only the chromosic oxide is deposited. Using a chromic chloride soln. with 100 grms. of Cr per litre, at the temp. of the room, and with current densities less than 0·072 amp. per sq. cm., the deposit consisted of metal mixed with more or less of the chromosic oxide; and with current densities 0·091 to 0·182 amp. per sq. cm., metal alone was deposited with a 38·4 to 38·6 per cent. ampère output. The deposit is good up to about 50°, but beyond that the chromium deposits as a black powder. With a constant current density and with soln. containing 184 grms. of Cr per litre and over, the deposit was a metallic powder; with soln. containing respectively 158, 135, and 105 grms. of Cr per litre, the percentage ampère outputs of pure metal were respectively 50·6, 49·0, and 38·4; with soln. containing 179 grms. of Cr per litre, at first metal and the chromosic oxide were deposited; and with 53 or less grms. of Cr per litre, chromosic oxide and hydrogen were formed. Sulphate and acetate soln. give similar results except the numerical values differed from those just indicated. The acetate soln. gave imperfect precipitates, and poor yields; the best yield—84·6 per cent.—with sulphate soln. occurred with soln. containing 65–85 grms. of Cr per litre, and a current density of 0·13 to 0·20 amp. per sq. cm. B. Neumann, and G. Glaser concluded that the influence of temp. is of slight importance, but H. R. Carveth and W. R. Mott found that with chloride soln. a rise of temp. caused a marked decrease in efficiency. The electrodeposition of chromium was also investigated by J. Sigrist and co-workers, and E. F. Smith. S. Kyropoulos found that chromium is deposited more freely in isolated spots on the crystal faces of tempered aluminium. A higher current density favours deposition on the crystal faces. Deposition on the crystal faces is favoured by conditions such that the production of hydrogen at the cathode is possible. Resistance to copper deposition is most clearly shown by passive chromium, deposition occurring only on isolated spots of non-passive chromium; with hydrogen evolution at the cathode, deposition occurs on the crystal faces of the chromium.

According to H. R. Carveth and W. R. Mott, in the electrolysis of a soln. of chromic chloride containing 100 grms. of Cr per litre, at 21°, and a current density of 0·5 amp. per sq. cm., the efficiency slowly increased until a constant value of about 30 per cent. was attained. This phenomena was attributed to the formation of chromous chloride which is assumed to be necessary for efficient electrolysis—raising the temp. acts deleteriously by increasing the rate of oxidation of chromous chloride. The bubbling of air through the soln. diminished the efficiency. Variations in the nature of the anode liquid caused considerable alterations in the efficiency; high values were obtained with an anolyte of ammonium sulphate, due, it is supposed, to diffusion into the cathode chamber. O. Dony-Hénault added that the formation of chromous chloride is not the only condition required for the deposition of chromium from a soln. of chromic salt. During the electrolysis of a soln. of chrome-alum, the green soln. becomes violet, and after a time deposits violet crystals of the alum. Chromium was deposited from the violet but not from the green soln.

According to J. Voisin, the electrolysis of a soln. of purified chromic acid gives 2 vols. of hydrogen and one vol. of oxygen as in the analogous case of sulphuric acid. The electrolysis of a soln. of ordinary chromic acid—260 grms. per litre—with a current density of 0·40 amp. per sq. cm. gives 0·250 grm. of white, adherent chromium per hour. Chromium anodes are preferable. The deposit is improved when 5–6 grms. of boric acid per litre are present. A sat. soln. of chromic hydroxide in hydrofluoric acid, and a current density of 0·2 to 0·20 amp. per sq. cm. and 12 volts gives no metal, but a green deposit of $Cr_2O_3.9H_2O$ appears on the cathode.

H. R. Carveth and B. E. Curry found that chromium begins to be deposited instantly from a soln. of impure chromic acid at 18° with a current density of about 0·80 amp. per sq. cm. The deposition is not so readily obtained with soln. of purified chromic acid which has a decomposition voltage of 2·31 volts. In all cases, the liquid was coloured brown, and chromic salts were produced; the brown precipitate formed at the cathode is probably $Cr(CrO_4)$. It is assumed that sexivalent chromium cations are present in the soln. of chromic acid, and that the increased deposition which occurs when sulphuric acid is present, is due to an increase in the conc. of the sexivalent Cr-cations by a reaction of chromic acid with the sulphuric acid. F. Salzer found that the deposits of chromium are produced with a bath of approximately equal proportions of chromic acid and chromic oxide; or preferably with an excess of chromic acid. The quantities should be kept nearly constant during the electrolysis, and the temp. maintained constant by cooling the bath. Anodes, capable of oxidizing the chromium oxide to chromic acid during the passage of the current, may be employed, in order to maintain a constant composition in the bath by compensating for the chromic acid reduced at the cathode, or insoluble anodes, such as lead or platinum, may be used to maintain a constant composition, these being in part freely suspended in the bath, and in part separated from the cathode chamber by convenient diaphragms. The subject was investigated by E. Liebreich, E. Müller, E. Müller and P. Ekwall, and G. Grube and G. Breitinger.

A. Krupp prepared chromium of a high degree of purity by electrolyzing a fused chromium halide using impure chromium as anode. The electrodeposition of chromium has been investigated by R. Appel,[3] C. L. Long and co-workers, G. Neuendorff and F. Sauerwald, and F. Andersen. R. Taft and H. Barham studied the electrodeposition of chromium from soln. of its salts in liquid ammonia.

H. Moissan, and J. Férée prepared *pyrophoric* chromium by distilling the amalgam in vacuo at 300°, but if heated more strongly, it loses its pyrophoric activity. H. Küzel obtained **colloidal chromium** by bringing the element to a fine state of subdivision by grinding, or by cathodic disintegration. It was then converted into the colloidal state by repeated alternate treatments for long periods with dil. acid soln. and dil. alkaline or neutral soln., under the influence of moderate heat and violent agitation. After each treatment the material was washed with distilled water or other solvent until completely free from the reagent employed. T. Svedberg also prepared **chromium hydrosol** by his process of cathodic disintegration; and with isobutyl alcohol as the liquid menstruum, **chromium** *iso***butylalcosol** was obtained. G. Bredig did not obtain much success with splutterings from an electric arc under water.

§ 4. The Physical Properties of Chromium

The specimens of chromium prepared by the early investigators were more or less impure, and in some cases the impurity affected the physical properties to an appreciable extent. The metal prepared by the carbon reduction process is contaminated with carbon or carbides; and that prepared by aluminium reduction is contaminated with aluminium and silicon. Chromium prepared by heating the amalgam to about 300° is a black pyrophoric grey powder—*vide supra.* R. Bunsen[1] found that the electrolytically deposited metal to be steel-grey or silver-white. H. Moser described chromium as a steel-grey mass composed of four-sided prisms; and J. F. Gmelin obtained a metal with a dull-grey fracture and interspersed with tin-white crystals. E. Glatzel obtained chromium as a micro-crystalline, grey powder; F. Wöhler obtained it in the form of what he called grey rhombohedra; E. Jäger and G. Krüss, tin-white rhombohedra; P. A. Bolley, tetragonal pyramids; E. Frémy, and E. Zettnow, in cubic crystals; and W. Prinz said that when prepared by F. Wöhler's process, the minute cubes with pyramidal faces furnish hexagonal and octahedral contours when examined by transmitted light; and he added that the supposed rhombohedra are probably deformed octahedra. W. C. Phebus and F. C. Blake found that the **X-radiogram** agrees with a body-centred cubic lattice, with side a=2·875 A. A. W. Hull gave for the side of the elementary cube of the body-centred cubic lattice, 2·895 A.; for the distance between the nearest atoms, 2·508 A.; and for the density, 7·07; R. A. Patterson, and F. Sillers gave a=2·872 A.; E. C. Bain, a=2·899 A.; and W. C. Phebus and F. C. Blake, a=2·875 A. for the body-centred cubic lattice. W. P. Davey and T. A. Wilson, E. Schmid, R. Blix, W. Hume-Rothery, and G. F. Hüttig and F. Brodkorb made observations on this subject. H. L. Cox and I. Backhurst observed no marked effect on the X-radiograms for stresses below the elastic limit. A. J. Bradley and E. F. Ollard said that the electro-deposited chromium may exhibit **allotropy,** for it may show the hexagonal structure as well as the body-centred cubic structure. C. S. Smith observed only the latter form. The subject was discussed by F. Adcock; and H. Shoji studied the mechanism of the change of the space-lattice in passing from one allotropic form to another. A. W. Hull added that iron and chromium have a similar arrangement of atoms in the space-lattice, and this shows that ferro-magnetism does not depend on a particular arrangement of the atoms. On the other hand, A. J. Bradley and E. F. Ollard said that the X-radiogram agrees with the assumption that chromium is a mixture of two allotropes. In the predominating form, the atoms are arranged in two hexagonal lattices giving an almost hexagonal close-packed structure, the axial ratio $a:c$ being 1·625 instead of 1·633, and the distance between neighbouring atomic centres 2·714 A. and 2·70 A.

J. B. Richter gave 5·9 for the **specific gravity** of chromium; F. Wöhler, 6·81 at 25°; J. E. Loughlin, 6·2; C. F. Rammelsberg, 6·522; R. Bunsen, 6·7; E. Glatzel, 6·7179–6·737 at 16° for the crystalline powder; A. Gotta, 7·0367 to 7·0747 at 25°; H. Moissan, 6·92 at 20° for the metal previously fused in an electric furnace; A. Binet du Jassonneix, 7·1 at 17° for metal derived from the boride; and T. Döring 7·085 for 98 per cent. chromium prepared by the alumina-thermite process. K. Honda gave 6·8 for a sample with over 20 per cent. of iron. K. Ruf gave 7·014 at 20° for the pure metal, and 7·011 for electrolytic chromium. G. F. Hüttig and F. Brodkorb found that electrolytic chromium free from occluded gas had a sp. gr. of 7·138 at 25°/4°, and 7·156 at —50°/4°; hence the **atomic volume** is 7·286 at 25° and 7·268 at —50°. H. Schröder discussed the volume relations of the sulphates, selenates, and chromates; E. Donath and J. Mayrhofer, the at. vol.; and I. Traube, the at. soln. vol. E. M. Baker and A. M. Rente, and D. J. Macnaughtan discussed the porosity of electro-deposited chromium. M. L. Huggins calculated for the **atomic radius,** 1·44 A.; W. F. de Jong and H. W. V. Willems, 1·40 A. to 1·42 A.; and W. L. Bragg, 1·40 A. H. G. Grimm, V. M. Goldschmidt, L. Pauling, E. T. Wherry, J. C. Slater, and A. M. Berkenheim discussed this subject, from which it follows that for sexivalent chromium atoms, the effective at. radius is 0·52 to 0·65 A., and for typical atoms, 1·17 to 1·54 A. P. Vinassa studied the mol. number.

K. W. Schwartz said that the bluish-white metal is exceedingly hard and can be drilled only with difficulty. J. B. Dumas found that the chromium he prepared scratched glass of hardness 5·6 on Mohs' scale. H. St. C. Deville said that its **hardness** is equal to that of corundum; while H. Moissan said that it scratches glass only with difficulty; it can be polished readily and then shows a good reflecting surface. J. R. Rydberg gave 9 for its degree of hardness (diamond 10). According to F. Adcock, the great hardness of electrolytically-deposited chromium, 650 on Brinell's scale, is apparently caused by the occluded hydrogen, the crystalline form, and possibly the oxygen. It is not possessed by the metal of a high degree of purity melted or annealed at high temp. in vacuo or an atm. of hydrogen, the hardness being then as low as 70 on Brinell's scale. L. E. and L. F. Grant obtained the hardest deposits of chromium from a soln. of 209 grms. of chromic acid, 23 grms. of chromic oxide, and 6·4 grms. of chromic sulphate per litre using a current density of 33·3 amps. per sq. dm., at 45°. D. J. Macnaughtan and A. W. Hothersall gave 500 to 900 for Brinell's hardness of electro-deposited chromium; and D. J. Macnaughtan studied the porosity of the deposits. The subject was discussed by R. J. Piersol. W. Treitschke and G. Tammann found that the **viscosity** of chromium is very great when in the vicinity of the m.p. T. W. Richards found the **compressibility** of chromium, *i.e.* the mean change of vol. per megabar, between 100 and 600 megabars, to be $0\cdot7\times10^{-6}$ for 99 per cent. chromium. P. W. Bridgman found for the vol. compressibility from measurements of the linear compressibility, at 30°, $\delta v/v_0=-5\cdot187\times10^{-7}p+2\cdot19\times10^{-12}p^2$; and at 75°, $\delta v/v_0=-5\cdot310\times10^{-7}p+2\cdot19\times10^{-12}p^2$. These values are lower than the result given by T. W. Richards. W. Widder gave for the modulus of elasticity, $E=E_{20}\{1-0\cdot006536(\theta-20)\}$; M. Grube, C. J. Smithells and S. V. Williams, J. Laissus, W. van Drunen, and F. C. Kelley studied the **diffusion** of chromium with iron and nickel.

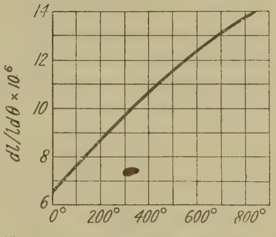

FIG. 2.—The Effect of Temperature on the Coefficient of Expansion.

J. Disch[2] found the coeff. of **thermal expansion**—linear—to be $0\cdot0_5731$ between —78° and 0°; and $0\cdot0_584$ between 0° and 100°. P. Chevenard found that the expansion curve is exactly reversible between 0° and 100° and shows no singular point. The true coeff. of expansion, 0·0000068 at 0°, increases rapidly with temp. and shows a slight concavity towards the increasing temp., Fig. 2. G. F. Hüttig and F. Brodkorb gave $1\cdot2\times10^{-5}$ for the coeff. of expansion between —50° and 25°. W. Widder gave $0\cdot0_5824$ at 20°. J. Disch gave for the linear expansion in mm. per metre:

	—78°	0°	100°	200°	300°	400°	500°
Expansion .	—0·57	0·00	0·84	0·75	2·72	3·76	4·86 mm.

E. Jäger and G. Krüss gave for the **specific heat** 0·12162 between 0° and 98·24°; H. Mache, 0·1208 between 0° and 100°; H. Schimpff 0·1044 at 0°; R. Lämmel gave 0·0898 at —100°; 0·1039 at 0°, and 0·1872 at 600°. T. W. Richards and F. G. Jackson, 0·0794 between —188° and 20°; and P. Schübel gave for the true sp. ht., c_p, and the **atomic heat**, C_p:

	50°	100°	200°	300°	400°	500°	600°
c_p .	0·1080	0·1160	0·1200	0·1211	0·1250	0·1340	0·1500
C_p .	0·63	6·05	6·25	6·30	6·50	6·99	7·81

S. Umino gave:

	100°	300°	500°	700°	900°	1100°	1300°	1500°	1640°
Sp. ht. .	0·118	0·123	0·131	0·144	0·158	0·177	0·200	0·225	0·187

F. Wüst, A. Meuthen and R. Durrer, and G. Tammann and A. Rohmann also made observations on the sp. ht. F. Michand, J. Maydel, and E. van Aubel discussed the at. ht. relations; and E. D. Eastman and co-workers, the thermal energy of the electrons in chromium, and computed $C_p—C_v=0·037$ Cal. per degree per mol. P. Nordmeyer and A. L. Bernoulli gave 0·1039 for the sp. ht. at 0°; 0·1121 at 100°; 0·1236 at 300°; 0·1503 at 500°; and 0·0860 between —185° and 20°. J. Dewar gave 0·0142 between —253° and 196° with the at. ht. 4·14. F. Simon and M. Ruhemann gave $C_p=1·249$ and $C_v=1·247$ at 71·29° K.; and $C_p=1·56$ and $C_v=1·56$ at 79·50° K. R. Lämmel represented his results by $c_p=0·103944+0·0_310591\theta—0·0_629694\theta^2+0·0_954088\theta^3$; and F. W. Adler observed:

	0°	100°	200°	300°	400°	500°	600°
c_p .	0·10394	1·11211	0·11758	0·12360	0·13343	0·15030	0·18710
C_p .	5·40	5·83	6·11	6·43	6·94	7·82	9·73

H. St. C. Deville[3] found that chromium melts at a higher temp. than is the case with manganese or platinum; and H. Moissan also stated that the **melting point** of chromium is much higher than that of platinum; for it cannot be fused by the oxyhydrogen blowpipe. E. Glatzel, however, fused it by the oxyhydrogen flame. S. O. Cowper-Cowles gave 2000° for the m.p.; but this is too high. E. A. Lewis found that the metal made by the aluminium-thermite process melted at 1515°±5°. G. K. Burgess gave for 99 per cent. chromium, 1489°; E. Tiede and E. Birnbräuer, 1420°; E. Newbery and J. N. Pring, 1615°±15°; W. Treitschke and G. Tammann, 1513°; S. Umino, 1600° (95·39 per cent. Cr); R. S. Williams, and G. Voss, 1553°; K. Lewkonja, 1547°; J. Johnston, 1510°; G. Hindrichs, 1550°; and R. Vogel and E. Trilling give 1575°. K. Honda gave 1515° for a sample with about 20 per cent. of iron. W. Guertler and M. Pirini, W. R. Mott, and G. K. Burgess and R. G. Waltenberg gave for the best representative value 1520°; but L. I. Dana and P. D. Foote gave 1615°. A. von Vogesack said that the m.p. of chromium is over 1700°, and that the lower values are due to the presence of carbon obtained from the carbon monoxide in the atmosphere in which the metal is melted; whilst with C. J. Smithells and S. V. Williams, 1920° was thought to be a low value for the m.p. H. Moissan said that when chromium is fused in the electric arc-furnace it forms a very fluid, bright liquid with the appearance and fluidity of mercury; and it can be cast in a mould. It can be distilled in the electric arc-furnace; and H. C. Greenwood gave 2200° for the **boiling point** of chromium—W. R. Mott estimated 3000°. J. Johnston gave for the **vapour pressure** $\log p=—14900T^{-1}+8·91$; and

	980°	1090°	1230°	1400°	1610°	1800°	1890°	2200°
p .	10^{-3}	10^{-2}	10^{-1}	1	10	50	100	760

F. Wüst and co-workers, and W. Herz gave 32·00 Cals. for the latent **heat of fusion** per gram; and S. Umino, 70·05 Cals. E. Kordes gave 0·91 (cals.) for the entropy of chromium. G. N. Lewis and co-workers gave 5·8 for the at. **entropy** of chromium at 25°; W. Herz, 10·85; and B. Bruzs, 19·8 at the m.p. E. D. Eastman and co-workers studied this subject; and R. D. Kleeman, the internal and free energy of chromium.

A. L. Bernoulli[4] gave 2·67 for the **index of refraction** of chromium, and 1·63 for the absorption coeff. for Na-light. H. von Wartenberg gave 2·97 for the index of refraction, μ; 4·85 for the absorption coeff., k; and 69·7 per cent. for the **reflecting power,** R. V. Fréedericksz gave

λ	257$\mu\mu$	325$\mu\mu$	361$\mu\mu$	444$\mu\mu$	502$\mu\mu$	668$\mu\mu$
μ	1·641	1·259	1·530	2·363	2·928	3·281
k	3·69	2·91	3·21	4·44	4·55	4·30

W. W. Coblentz and R. Stair, and W. W. Coblentz gave for the **reflecting power**

λ	0·5μ	1·0μ	2·0μ	3·0μ	4·0μ	5·0μ	9·0μ
R	55	57	63	70	76	81	92 per cent.

P. R. Gleason, W. W. Coblentz and R. Stair, and M. Luckiesh made observations on the subject. V. Fréedericksz gave 60 to 72 per cent. for λ=257$\mu\mu$ to 668$\mu\mu$. F. J. Michéli observed no difference between the reflecting power of passive and active chromium, although in the case of passive and active iron, the results indicated that a film was formed. A. L. Bernoulli found that the results of F. J. Michéli were anomalous owing to gas absorption, for there is a marked difference in the reflecting powers of the active and passive forms of chromium—this is attributed to the presence of a surface film on the passive metal. J. H. Gladstone found the **refraction equivalent** of chromium to be 15·9; and the **specific refraction,** 0·305. W. J. Pope gave 22·25 for the refraction eq. of tervalent chromium. T. Bayley,[5] and M. N. Saha discussed the colour relations of chromium and of copper, manganese, iron, cobalt, and nickel; and J. Piccard and E. Thomas, of chromous and chromic ions, and of chromates and dichromates. W. Biltz discussed the relation between colour and the magnetic properties of the element.

Chromium compounds do not give the ordinary **flame spectrum.** V. Merz[6] said that when a chromate moistened with sulphuric acid is introduced at the edge of the colourless gas flame, the edge of the flame acquires a dark reddish-brown colour and a rose-red mantle which can be recognized with 0·001 mgrm. of the chromate. K. Someya observed that the colourless soln. obtained by reducing a very dil. soln. of potassium dichromate shows that chromous ions are colourless, and that thiocyanate produces the blue colour of conc. soln. owing to the formation of complex ions. F. Gottschalk and E. Drechsel found that the vapour of chromyl chloride in the oxy-coal gas flame shows a band spectrum in the green and yellow. A. Gouy found that when chromium salts are fed into the bunsen flame, the inner cone shows some spectral lines. J. N. Lockyer also found spectral bands with chromium salts in the oxy-coal gas flame, and G. D. Liveing and J. Dewar observed numerous lines in the specimen of the explosion flame of electrolytic gas with chromium salts. W. N. Hartley observed the oxy-hydrogen flame spectrum. H. W. Vogel, M. A. Catalan, and C. de Watteville studied this subject. G. Kirchhoff first investigated the **spark spectrum,** and he was followed by W. A. Miller, W. Huggins, R. Thalén, C. C. Kiess, A. Mitscherlich, L. de Boisbaudran, G. Ciamician, J. Parry and A. E. Tucker, G. D. Liveing and J. Dewar, J. N. Lockyer, F. McClean, E. Demarçay, L. and E. Bloch, A. de Gramont, W. E. Adeney, R. J. Lang, O. Lohse, F. Exner and E. Haschek, R. E. Loving, A. Hagenbach and H. Konen, M. A. Catalan, J. H. Pollock, J. H. Pollock and A. G. G. Leonhard, F. L. Cooper, J. M. Eder and E. Valenta, and H. Smith. The simple spark spectrum shown by, say, a soln. of chromic chloride is characteristic, and can be employed in the spectroscopic detection of chromium, Fig. 3. There is the 5207-line in the green; and a group of three

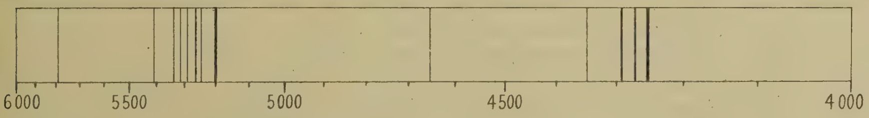

FIG. 3.—Spark Spectrum of Chromium.

lines 4290, 4275, and 4254 in the indigo-blue, which are well defined, while there are feebler lines 4345 in the blue; 5253, 5276, 5297, 5341, and 5410 in the green; and 5790 in the orange-yellow. E. O. Hulburt studied the spectrum of the condensed spark in aq. soln. The **arc spectrum** of chromium was studied by J. N. Lockyer, B. Hasselberg, F. Exner and E. Haschek, M. A. Catalan, H. Gieseler, Lord Blythwood and W. A. Scoble, R. Frerichs, A. S. King, A. B. McLay, J. Clodius, D. Foster, L. Stüting, K. Burns, S. P. de Rubies, J. Buchholz, C. C. Kiess, C. C. Kiess and W. F. Meggers, and J. Hall. The **ultra-violet spectrum** was studied by W. A. Miller, J. C. McLennan, A. B. McLay, R. A. Millikan and I. S. Bowen, V. Schumann, F. Exner and E. Haschek, L. and E. Bloch, W. E. Adeney, M. Edlen and M. Ericson, and R. Richter; the **ultra-red spectrum,** by K. W. Meissner, T. Dreisch, and H. M. Randall and E. F. Barker. H. Finger examined the effect of the *medium* on the lines in the spark spectrum; F. Croze, M. A. Catalan, and A. de Gramont, *les raies ultimes*, and *les raies de grand sensibilité;* G. D. Liveing and J. Dewar, the *reversed lines* in metal vapours; J. N. Lockyer and F. E. Baxandall, M. Kimura and G. Nakamura, and J. N. Lockyer, the *enhanced lines;* A. S. King, and H. Geieler, the *anomalous dispersion;* W. J. Humphreys, the effect of *pressure;* J. A. Anderson, and H. Nagaoka and Y. Sugiura, the **Stark effect** or the influence of an *electric field* on the arc spectrum; and A. Dufour, H. du Bois and G. J. Elias, W. Miller, J. E. Purvis, C. Wali-Mohammad, O. Lüttig, W. C. van Geel, E. Krömer, and W. Hartmann, the **Zeeman effect.** The **absorption spectrum** of the vapour was examined by J. N. Lockyer and W. C. Roberts-Austen, R. V. Zumstein, H. D. Babcock, A. S. King, A. W. Smith and M. Muskat, H. Gieseler and W. Grotrian, and W. Gerlach; the absorption spectrum of aq. soln. of various salts (*q.v.*) was examined by W. de W. Abney and E. R. Festing, W. Ackroyd, T. Bayley, H. Becquerel, W. Böhlendorff, H. Bremer, D. Brewster, A. Byk and H. Jaffe, T. Carnelley, S. Kato, H. Croft, T. Erhard, A. Étard, J. Formanek, J. Gay, J. H. Gladstone, F. Hamburger, A. Hantzsch, A. Hantzsch and R. H. Clark, W. N. Hartley, J. M. Hiebendaal, H. C. Jones and W. W. Strong, G. Joos, B. Käbitz, O. Knoblanch, W. Lapraik, H. Fromherz, G. D. Liveing and J. Dewar, G. Magnanini, G. Magnanini and T. Bentivoglio, F. Melde, W. A. Miller, H. Moissan, J. Müller, E. L. Nichols, C. Pulfrich, A. Recoura, G. B. Rizzo, P. Sabatier, C. A. Schunck, H. Settegast, C. P. Smyth, J. L. Soret, G. J. Stoney and J. E. Reynolds, H. F. Talbot, H. M. Vernon, K. Vierordt, E. Viterbi and G. Krausz, H. W. Vogel, E. Wiedemann, and C. Zimmermann; and the absorption lines in the spark spectrum under water, by E. O. Hulburt. J. Formanek said that the chromium salts do not react with alkanna tincture. L. de Boisbaudran examined the **fluorescence spectrum.** According to T. Tanaka, chromium is the principal agent in the cathodoluminescence of corundum. No **series spectrum** has been observed with chromium, but the lines have been studied from this point of view by L. Janicki, A. Dufour, P. G. Nutting, H. N. Russell, S. Goudsmit, E. Krömer, M. Steenbeck, H. Deslandres, A. Sommerfeld, H. E. White, H. E. White and R. C. Gibbs, M. A. Catalan, R. Mecke, H. Gieseler, R. Frerichs, R. J. Lang, C. V. Ramon and S. K. Datta, G. Wentzel, Y. M. Woo, C. Wali-Mohammed, H. Pickhan, C. C. and H. Kiess, A. de Gramont, O. Laporte, W. F. Meggers and co-workers, A. E. Ruark and R. L. Chenault, C. C. Kiess and O. Laporte, R. J. Lang, M. A. Catalan, C. E. Hesthal, and N. Seljakoff and A. Krasnikoff.

B. Rosen,[7] M. Levi, and G. Kettmann studied the **X-ray spectrum**. The K-series in the X-ray spectrum was studied by V. Dolejsek, V. Dolejsek and K. Pestrecoff, B. C. Mukherjee and B. B. Ray, M. Steenbeck, C. G. J. Moseley, W. Duane and co-workers, D. Coster, G. Wentzel, N. Selijakoff and A. Krasnikoff, E. C. Unnewehr, A. E. Lindh, H. Fricke, S. Eriksson, T. L. de Bruin, W. Bothe, B. Kievit and G. A. Lindsay, F. Wisshak, S. Pastorello, J. H. van Vleck and A. Frank, H. Beuthe, H. R. Robinson and C. L. Young, N. Seljakoff and co-workers, M. J. Druyvesteyn, R. C. Gibbs and H. E. White, F. Hjalmar, K. Chamberlain, O. Stelling, M. Siegbahn and co-workers, B. Walter, J. Schrör, and H. Stensson. There are the lines $\alpha_2\alpha'=2{\cdot}28855$; $\alpha_1\alpha=2{\cdot}28517$; $\alpha_3\alpha_4=2{\cdot}2733$; $\beta_1\beta=2{\cdot}08144$; and $\beta_2\gamma=2{\cdot}069$. The L-series was examined by J. Schrör, A. Duvanlier, C. E. Howe, F. de Boer, F. P. Mulder, G. Kellström, F. L. Hunt, and R. Thoroeus; the M-series, by F. P. Mulder, and B. C. Mukherjee and B. B. Ray; the N-series, by F. P. Mulder; and the O-series, by F. P. Mulder.

U. Andrewes and co-workers [8] studied the absorption of **X-rays.** The absorption coefficients of X-rays from chromium radiator were studied by U. Andrewes and co-workers, D. M. Bose, C. G. Barkla and C. A. Sadler, and T. E. Aurén. O. W. Richardson and F. S. Robertson investigated the soft X-rays from chromium. A. C. Davies and F. Horton gave the critical potentials for soft X-rays. J. C. McLennan, and M. A. Catalan gave 6·7 volts for the **ionization potential,** and 2·89 volts for the first **resonance potential.** H. N. Russell gave 6·74 volts for the first ionization potential and 16·6 volts for the second. B. B. Ray and R. C. Mazumdar discussed the critical potential; E. Rupp, the deflection of electrons by films of chromium; and R. H. Ghosh, and B. B. Ray and R. C. Mazumdar, the relation between the ionizing potential and the electronic structure. E. Rabinowitsch and E. Thilo studied the subject. J. E. P. Wagstaff gave $8{\cdot}3\times10^{12}$ for the **vibration frequency;** and W. Herz, $8{\cdot}43\times10^{12}$. According to R. Whiddington, the critical velocities of cathode rays required to excite K- and L-radiations with the chromium radiator are respectively $5{\cdot}0\times10^9$ and $2{\cdot}0\times10^8$ cm. per sec. E. C. Unnewehr studied the dependence of the energy of emission of the K-radiation on the applied voltage. The use of chromium as a radiator for X-rays was discussed by R. Whiddington, and C. A. Sadler and A. J. Steven. A. Wehnelt classed chromic oxide as an "inactive oxide" so far as the emission of electrons is concerned, when it is fixed on a platinum disc and used as a cathode of a discharge tube; but A. Poirot found that **anode rays** are emitted from chromium. W. Espe studied the subject. E. Rupp discussed the passage of electrons through thin films of chromium. P. Weiss and G. Foex calculated values for the **atomic moments;** O. W. Richardson and F. S. Robertson studied the **photoelectric effect,** and U. Nakaya examined the influence of adsorbed gas on this phenomenon. R. E. Nyswander and B. E. Cohn studied the thermoluminescence of glass activated with chromium.

P. E. Shaw and C. S. Jex [9] said that chromium acquires negative **triboelectricity** when rubbed on glass. K. F. Herzfeld discussed the metallic conductivity of chromium. I. I. Shukoff gave $38{\cdot}5\times10$ mhos for the **electrical conductivity** of chromium at 0°; and A. Schulze gave $2{\cdot}60\times10^{-6}$ for the sp. resistance at 0°. J. C. McLennan and C. D. Niven gave for the sp. resistance, R, of aged and unaged chromium:

		29°	27°	−152·4°	−193°	−190°	−268·8°	−269·99°	−270·8°
R	aged .	17·2	—	0·90	2·01	—	—	—	—
	unaged .	—	43·8	27·0	—	28·8	26·7	26·6	26·5

They observed no indication of superconductivity at low temp. P. W. Bridgman gave $-5{\cdot}8\times10^{-7}$ for the press. coeff. of the resistance; and 0·000033 for the temp. coeff., the resistance at 30° being 160×10^5. The values are taken to represent an impure metal. J. C. McLennan and co-workers found for the resistance of aged chromium, at different temp. absolute, to be:

	292°	273°	80°	20·6°	4·2°	2·25° K.
$R\times10^3$ . .	5·59	—	0·655	0·260	0·258	0·258 ohms
Sp. resistance .	17·2	15·25	2·01	0·80	0·79	0·79

The values of the ratio R/R_0 at liquid air temp. is 0·132, and at liquid hydrogen temp., 0·059. P. Kapitza examined the effect of a magnetic field on the electrical conductivity. Z. A. Epstein compared the electrical conductivities of the elements and their position in the periodic table. K. Hopfgartner found that the transport numbers of the chromic ion in hydrochloric acid soln., are 0·318, 0·357, and 0·414 respectively for 1·00, 0·32, and 0·075 eq. soln.—*i.e.* for zero concentration, 0·446.

The mobility of the chromic ion is 46·3 to 53. It is assumed that the chromic ion is surrounded by a fairly large water-sheath. E. Newbery discussed the over-voltage; S. J. French and L. Kahlenberg, the gas-metal electrodes obtained by chromium and oxygen, nitrogen, or hydrogen; and N. Koboseff and N. I. Nebrassoff, the cathodic polarization.

According to J. J. Berzelius, there are two allotropic forms of chromium. The one, α-**chromium,** obtained as a grey metallic powder by reducing chromium trichloride with potassium, inflames between 200° and 300° and burns vividly to chromic oxide, and it dissolves readily in hydrochloric acid with the evolution of hydrogen; the other, β-**chromium,** obtained by reduction with carbon at a high temp., cannot be oxidized by heat, by boiling with aqua regia, by hydrofluoric acid, or by ignition with potassium hydroxide or nitrate. He added that corresponding modifications can be traced through many of the compounds of chromium; but this statement is not now regarded as correct because certain allotropic forms of the salt are now explained without assuming that they are due to allotropic forms of the element. As indicated above, R. Bunsen asked if the electrolysis of soln. of the green and violet chromium salts would give corresponding allotropic forms of the element, but the answer is in the negative. W. Hittorf recognized that chromium can exist in an active and in a **passive state.** Chromium is active in contact with hydrofluoric, hydrochloric, hydrobromic, hydriodic, acetic, oxalic, sulphuric, and hydrofluosilicic acids, that is, the metal dissolves in these acids with the evolution of hydrogen, if the acids are concentrated and cold, and if the acids are dilute, application of heat may be required. On the other hand, chromium is passive in chlorine or bromine water, in conc. nitric, chromic, phosphoric, chloric, perchloric, citric, formic, or tartaric acid, for the metal does not dissolve therein. The difference in its behaviour towards these acids is associated with a difference in the electrode potential of chromium for the difference in the e.m.f. of the two states amounts to about 1·6 volts, for with active chromium, the e.m.f. of the cell Cr/acid, H_2CrO_4/Pt is about 1·9 volt, and with the passive metal, 0·3 volt. In the electrochemical series, active chromium is close to zinc, but passive chromium stands near platinum. Otherwise expressed, passive chromium behaves as a noble metal, being electronegative towards zinc, cadmium, iron, nickel, copper, mercury, and silver, for it does not decompose even boiling soln. of these salts, excepting that it reduces mercuric and cupric salts respectively to mercurous and cuprous salts. When chromium is employed as anode in soln. in which it is indifferent, it becomes covered with a yellow film of chromic acid, and the loss of weight of the anode was found to correspond with the production of sexivalent chromium ions; this occurs even in soln. of hydrogen chloride in which chromium ordinarily dissolves with the formation of chromous salts. This may be due either to the decomposition of the water by the anion and subsequent formation of chromic acid from the liberated oxygen, or to the formation of a compound of sexivalent chromium with the anion and the decomposition of this compound by water; no such compound, however, is actually known to exist. In soln. of potassium thiocyanate or of an iodide, the chromium anode experiences no loss. The coeff. of the amalgamated metal M in the cell M | KCl, $NaNO_3$, $AgNO_3$ | Ag at 5° are:

M .	Zn	Cd	Pt	Fe	Sn	Cu	Cr
Volt .	1·534	0·974	1·123	0·955	1·010	0·689	0

W. J. Müller found that there are certain current densities which vary with the time required to make the metal passive. W. Muthmann and F. Fraunberger found the electrode potential between chromium and N-KCl against the normal calomel electrode zero to be $-0·63$ volt for the most active metal, and $+1·19$ volt for the most passive. Fresh electrolytic chromium was found by B. Neumann to be strongly active. W. Muthmann and F. Fraunberger observed variations of the electrode potential with the same piece of metal. A piece 25 cms. long had a potential of $-0·03$ volt at one end, and $+0·03$ at the other; and when activated,

—0·17 volt and —0·07 volt. W. Rathert observed that a piece of chromium polished in air had a potential against 0·1N-H_2SO_4 of +0·26 volt, and after lying some time in air, +0·37 volt; and when polished, in hydrogen, —0·054 volt at first, and +0·071 after standing 3 minutes in the liquid. Thus, polished chromium is not active in hydrogen. Passive chromium becomes active when it is charged electrolytically with hydrogen; but molecular hydrogen has scarcely any action on the potential of a passive chromium electrode. A. M. Hasebrink observed that when chromium is treated with nitric acid, and heated in nitrogen, it remains active a few hours, and then becomes passive; if hydrochloric acid be substituted for nitric acid, the chromium remains active as long as it is kept in nitrogen. Chromium activated in hydrogen remains active in this gas. At ordinary temp., nitrogen, hydrogen, and carbon dioxide do not activate chromium, nor do they passivate chromium made active by scratching. Occluded gases influence the rate of activation or passivation of chromium. Oxygen favours passivation, hydrogen retards it. Atm. oxygen rapidly passivates chromium; iodine acts as an activating agent, never as a passivating agent. The potential of chromium or nickel rubbed with emery in an indifferent atm., falls at first, then recovers partially; and after repeated rubbings, a constant potential is finally reached which is lower than the initial one. Molecular oxygen passed through an electrolyte, during the electrolysis of chromium, raises its potential; but the potential is scarcely affected if hydrogen or nitrogen be employed in place of oxygen. Electrolytic oxygen or hydrogen affect the potential enormously. The subject was discussed by T. Murakami, and B. Strauss and J. Hinnüber.

As previously indicated, chromium becomes passive when treated with certain oxidizing agents—*e.g.* chlorine or bromine-water, soln. of iodine and potassium iodide, conc. nitric and chromic acids, chloric acid, potassium permanganate, potassium ferricyanide, ferric chloride, and oxygen or air—N. Isgarischeff and A. Obrutscheva also found that oxidizing agents—like chromic acid, hydrogen dioxide, potassium permanganate—and exposure to air or to electrolytic oxygen make the metal passive; and, according to A. L. Bernoulli, the action of a soln. of quinine in benzene. Chromium also becomes passive when used as anode in an electrolytic cell. J. Alvarez found the strength of the current necessary to produce the passive state—the *critical strength of current*—depends on the conc. and temp. of the electrolyte. Thus, with 2·8N-, 0·7N-, and 0·175N-HCl, the critical voltages were 0·35, 0·085, and 0·034 volt respectively; and with 5N-, 0·6N-, and 0·075N-H_2SO_4, respectively 0·098, 0·046, and 0·018 volt. C. Fredenhagen applied a gradually increasing or decreasing e.m.f. to a chromium electrode immersed in sulphuric acid, and determined the electrode potential and the strength of the polarization current. The electrode potential at the point where activity or passivity sets in is not well-defined, and this is taken to support the hypothesis that passivity does not depend on the formation of an oxide film or of another modification of the metal, but is rather related to the rate at which the metal becomes charged with oxygen. The electrode potential attained when passivity or activity sets in is very sensitive to slight changes in the conc. of the acid; and a rise of temp. favours the active state. The passive condition is said to be attained when the oxygen polarization extends uniformly over the whole surface of the electrode; and the appearance of the active state when the polarization e.m.f. is lowered is due to the fact that the reactions which use up oxygen begin to overbalance those which produce oxygen. According to W. Rathert, the potential at which the passive metal becomes active is not the same as that at which the active metal becomes passive, and that the abrupt change observed by F. Flade does not represent a boundary potential below which the metal is active and above which it is passive. The metal may be active or passive on both sides of this point depending on its previous treatment. U. Sborgi and G. Cappon found that chromium in an ethyl alcohol soln. of calcium nitrate and ammonium nitrate is passive with low-current densities, and with high-current densities chromium salts are formed. E. Becker and H. Hilberg found that the maximum distance for establishing contact with a metal surface is slightly greater for passive than for active chromium.

According to W. Hittorf, and A. Meyer, and as indicated above, passive chromium is activated by soln. of hydrofluoric acid and of a number of other acids—*e.g.* hydrochloric, hydrobromic, hydriodic, sulphuric, and oxalic acids—by the halogens, and by raising the temp. The more dil. the acid, the higher the temp. necessary for activation; hydrogen is evolved, and chromous salts are formed. Soln. of the chlorides of the alkaline and alkaline earths act at a higher temp.; soln. of potassium bromide, cupric chloride or palladium dichloride do not act at 100°. The molten fluorides, chlorides, bromides, and iodides are good activating agents, and A. L. Bernoulli observed that chromium is activated when heated with benzene, toluene, naphthalene, and anthracene; and, according to N. Isgarischeff and A. Obrutscheva, when the surface is mechanically purified. The metal is activated by using it as cathode with indifferent acids like formic, citric, or phosphoric, *i.e.* by electrolytic reduction. The current required is greater the more dil. the soln., and the lower the temp. According to G. C. Schmidt, passive chromium becomes active by disturbing the surface, by scratching, knocking, and so on, but in nitric acid it remains permanently passive. Activated chromium placed in dil. hydrochloric or sulphuric acid remains permanently active. On removal from the acid, however, it becomes passive again after a short time, even although oxygen is rigorously kept away. Chromium heated in a vacuum or in nitrogen is active. In hydrochloric acid at 100° it is also active, and at this temp. chlorine, bromine, and iodine attack chromium and activate it, solely because the surface is disturbed. H. Eggert observed that chromium remains active in dry hydrogen, or nitrogen, but becomes passive if oxygen be present or if it be exposed to air. W. Rathert found that passive chromium becomes active when it has absorbed hydrogen ions by diffusion, and it then dissolves electrolytically in accord with Faraday's law. U. Sborgi and A. Borgia observed that a magnetic field had no influence.

Active chromium is indifferent towards water, but in strong acids it dissolves forming chromous salts, and in weak acids it dissolves when it is the cathode in an electrolytic cell, producing chromous salts: $Cr+2HCl=CrCl_2+H_2$. The dissolution of a chromium anode to form bivalent chromium ions is then in accord with Faraday's law so that $1Ag=\frac{1}{2}Cr$. The highest numerical value for the electrode potential observed by W. Muthmann and F. Fraunberger is —0·63 volt with N-KCl; B. Neumann observed —0·535 volt with chromic sulphate; —0·518 volt with chromic chloride; and —0·516 volt with chromic acetate; and W. Rathert obtained with N-$Cr_2(SO_4)_3$, —0·395 volt, and with 0·1N-H_2SO_4, —0·491 volt. The potential of the active metal towards normal soln. of $Cr^{\cdot\cdot}$-ions is —0·6 volt. N. Bouman gave —0·546 volt for chromium in N-H_2SO_4. This potential is independent of the metal on which the chromium is deposited, and also of the method of activation. It is also independent of the ratio of $Cr^{\cdot\cdot}$- to $Cr^{\cdot\cdot\cdot}$-ions in soln. It is curious that, with increasing hydrogen-ion concentration, the potential becomes more positive in sulphuric acid, but more negative in hydrochloric acid soln. Chromium remains active only when the acidity is above a certain limit, about 0·001N. A. H. W. Aten gave —0·75 volt, or, when referred to the hydrogen electrode, —0·47 volt. This active potential is attained only when sufficient hydrogen is present; hydrogen hastens the attainment of the electrode equilibrium. Active chromium can be anodically polarized in a soln. of potassium chloride without becoming passive. If the metal immersed in a soln. of chromous sulphate is anodically polarized with a sufficiently strong current, the chromium becomes passive, but when the current is interrupted, the potential of the metal is found to be more negative than before polarization. The passivation during anodic polarization and activation after this treatment are shown by chromium which has been deposited on copper, silver, or gold. The degree of activation after anodic polarization increases with the strength of the polarizing current. The resistance offered by the metal to the action of the polarizing current is greater when the strength of the current is gradually increased than when the current strength is increased rapidly. The resisting power of the metal is smaller when the chromium has been previously subjected to cathodic polarization. Active chromium reduces fused cadmium chloride, bromide, or iodide, and the chlorides of copper, silver, and lead ; as well as hot soln. of copper, gold, palladium, and platinum, and it thereby becomes passive. Passive chromium, as indicated above, differs from active chromium in that it is covered with a surface film of some kind, and it then behaves like a noble metal, for it does not dissolve in nitric, chloric, or perchloric acid ; it is indifferent towards neutral soln. of the salts of copper, silver, cadmium, mercury, and nickel—*vide supra* ; and it does not reduce soln. of the chlorides of gold, palladium, or platinum. It then appears to be a nobler metal than copper, silver, or mercury. The presence or absence of a film was discussed by W. J. Müller, and J. Hinnüber. W. Muthmann and F. Fraunberger observed that the electrode potential in N-KCl may be as great as +1·19 volt. N. Bouman found that in the passive state, the potential of chromium in potassium chloride soln. depends on the previous treatment which it has received, and this is shown to be equally true of other metals, including platinum. Consequently, no conclusions can be drawn from such measurements relative to the state of the metal. The potential of passive chromium varies with the metal on which it is deposited. When chromium is polarized anodically, the potential varies in the same way with the acidity as the potential of the unattackable electrode. The polarization tension is therefore governed by the reaction $Cr^{\cdots}+3H_2O=CrO_3+6H^{\cdot}+3(+)$. When passive chromium dissolves at the anode it forms chromic acid, and the dissolution is in accord with Faraday's law provided $1Ag=\frac{1}{6}Cr$. Otherwise expressed, passive chromium dissolves as sexivalent chromium ions. R. Luther said that the anode potential is +0·6 volt and energy is required for the reaction symbolized : $Cr+4H_2O\rightarrow H_2CrO_4+3H_2O$, or $Cr+4H_2O+6(+)\rightarrow CrO_4''+8H^{\cdot}$. The active and passive states are mutually convertible one into the other by a suitable change in the conditions. Thus, W. Rathert found that with active chromium dipping in N-$Cr_2(SO_4)_3$, the electrode potential at the beginning was —0·395 volt, and in 2, 23, and 73 min. was respectively —0·359, —0·209, and —0·129 volt ; and E. Grave found that passive chromium in 0·1N-KOH had an electrode potential of +1·895 volt at the beginning, after 20 sec. +1·176 volt, and after 1, 5, and 12 min. respectively +1·084, +0·981, and +0·925 volt. A. L. Bernoulli found that passive chromium is activated by aromatic hydrocarbons —benzene, toluene, *p*-xylene, naphthalene, and anthracene—and the changes in the e.m.f. are greater the more readily the hydrocarbon is oxidized. Active chromium becomes passive when treated with a boiling soln. of *p*-benzoquinone in benzene ; and also by exposure to air. According to A. H. W. Aten, if chromium has been rendered passive by anodic polarization, in a soln. of potassium chloride, the active condition may be restored by heating the soln. This change occurs even when the polarizing current is continued during the heating of the soln. and on cooling, the chromium remains in the active condition, provided the current is not too strong. U. Sborgi and G. Cappon found that in an alcoholic soln. of calcium or ammonium nitrate, chromium shows passivity phenomena similar to those which occur in aq. soln.

W. Hittorf concluded that the passivity of chromium is not due to the formation of an oxide film, but rather to the metal assuming a different electrical state ; the metal in the passive state is in a strained or coerced condition—*Zwangzustand*—so that instead of dissolving as a bivalent element it dissolves as a sexivalent element. The film hypothesis, discussed in connection with the passivity of iron, best fits the facts. C. W. Bennett and W. S. Burnham stated that the film is best regarded as a film of oxide which is rendered stable by adsorption into the metal. The oxide is usually unstable, but becomes stable when adsorbed by the metal. The oxide is not higher than CrO_3, and is probably $Cr(CrO_4)$, or CrO_2, but in the further oxidation at the anode, the higher oxide CrO_3 is formed, and the chromium passes into soln. in the sexivalent state. A. L. Bernoulli gave Cr_5O_9, or $2Cr_2O_3.CrO_3$, for the composition of the film. The subject has been discussed by A. Adler, F. Flade, C. Fredenhagen, E. Grave, W. J. Müller and co-workers, W. Rathert, O. Sackur, H. Kuessner, E. Newbery, G. C. Schmidt, etc.—*vide* iron. N. Bouman favoured the allotropic theory. According to N. Isgarischeff and A. Obrutscheva, chromium shows no definite transition point at which it passes into the active state; the metal can become active at any temp.; the activation depends on the properties of the medium. This and the mode of formation of passive chromium show that the passivity of chromium is connected with the formation of a protecting oxide film on the surface. The protecting film is a transparent, colloidal substance, the density and permanence, and consequently the passivating action, of which depend on the nature of the medium, particularly on the presence of those ions, such as chloride- and bromide-ions, which bring about colloidal transitions. Chloride-ions have the greatest disturbing effect on the film, and make it permeable to most reagents. Particles of passive chromium become active when brought into contact with active chromium zinc, or magnesium. Since these metals are all more electro-negative than passive chromium, this action is due to the formation of a galvanic element which liberates hydrogen and consequently reduces the oxide film. The oxide film is also the cause of the anomalies of chromium. E. Liebreich and W. Wiederholt plotted the current density against the potential of electrolytic chromium in $1{\cdot}02N$-K_2SO_4. At high current densities, the chromium dissolves as chromate, at lower current densities and potentials, Fig. 4, the metal acquires a film of the chromic chromate and dissolves only slightly at a potential of about 0·5 volt, and a small current density, the potential gives a slight rise with falling current density and true passivity, owing to the insolubility of a film of hydroxide, sets in. The passivity persists when the metal is made a cathode at small current densities. The curve for a potential of 0·4 volt rises steeply as the metal dissolves to form chromous salts which are partially oxidized near the electrode forming secondary hydrogen: $2CrSO_4+H_2SO_4=Cr_2(SO_4)_3+H_2$. At higher current densities, and at about $-0{\cdot}5$ volt, the metal dissolves forming hydrogen directly. G. Grube and co-workers found that with an active chromium electrode (prepared by cathodic polarization) with $0{\cdot}02$–$0{\cdot}2N$-sulphuric and hydrochloric acid soln., the anode potential is found to increase suddenly when the anode current density reaches a certain value. This critical value increases with the conc. of the acid and with increasing temp. During the first stage, the chromium ions pass into soln. entirely in the bivalent condition, and, during the second stage, entirely in the sexivalent condition. At the ordinary temp., N-NaCl behaves similarly, but at higher temp. the current density-potential curves are of somewhat different form. H. Kuessner suggested that it is possible for chromium ions of varying valency to be formed simultaneously in soln. G. Grube and co-workers hold that chromium goes primarily into soln. as bivalent ions at lower current densities, and that these are immediately oxidized to the tervalent condition, whilst at higher current densities sexivalent ions are formed. The anode potential in N-, $4N$-, $8N$-, and $16N$-potassium hydroxide soln. has also been studied at different temp.; for low current densities, the curve is discontinuous as in acid soln., and a similar explanation is adopted. In the alkaline soln., the anode becomes coated with a fine grey powder, which apparently consists

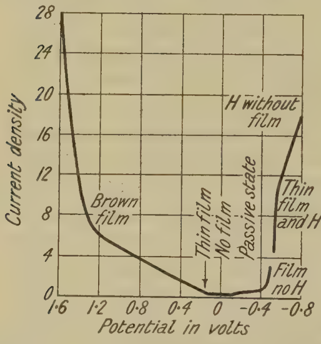

FIG. 4.—Current Density-Potential Curves of Chromium.

of a lower oxide of chromium. The facts support the oxide film theory of passivity. F. Krüger and E. Nähring found the X-radiograms of active and passive metal support the oxide-film theory. The subject was discussed by U. R. Evans. A. M. Hasebrink's chemical experiments favour the oxide film theory, but not the hydrogen theory, or the surface-tension theory of W. Hittorf, and G. C. Schmidt. L. McCulloch found cases of passivity with sparingly-soluble sulphate films.

A. S. Russell supposed that when in the active state, the atoms of chromium have two electrons in the fourth quantum orbit, and that when the metal becomes passive one of these electrons is removed to the third quantum orbit. The subject was studied by E. Müller, E. Liebreich, H. Eggert, and N. Isgarischeff and A. Obrutscheva. W. J. Müller and E. Noack found that with thermite chromium in N-H_2SO_4, so long as the current density falls below a certain critical value, i_c, which varied from sample to sample according to treatment, the metal remained active, and dissolved with the evolution of hydrogen. On exceeding this critical value, a fall of density immediately set in, during which the log of the density varied inversely as the time since the commencement of the fall, and after sufficient time complete passivity resulted. Log i_c was inversely proportional to the temp. between 0° and 35°. The activity of the chromium was characterized by a potential of $-0{\cdot}34$ volt, and passivity by zero potential, so that during the time of falling density, the metal remained active. In W. J. Müller's theory of the passivity of iron, the metal dissolves in the acid, but owing to the high mobility of the hydrogen ions, the anodic soln. becomes impoverished in these; hence basic ferrous salt is formed and deposits on the electrode when the soln. becomes saturated, thus increasing the resistance and decreasing the current, causing complete passivity only when the covering is complete. With chromium, the chromous salt first formed by dissolution of the metal in the acid rapidly oxidizes to chromic salt (hydrogen being evolved), which hydrolyzes much more rapidly than the iron salts; with high current densities (*e.g.* 1400 milliamp. per sq. cm.), the time required for passivity is only 0·3 sec. With perfectly clean metal the fall of current density is often suspended for a time and then occurs suddenly; this is explained by the supersaturation of the soln. with regard to hydroxide, which would be possible only in the absence of impurities.

According to J. L. R. Morgan and W. A. Duff,[10] when two electrodes—one of chromium and one of platinum—are immersed in dil. sulphuric acid, the current passes freely when platinum is made the anode, but if chromium is made the anode no current passes through the cell. If the applied e.m.f. be gradually increased when chromium is the anode, no current passes until about 75 volts are attained; if the increase is made so rapid that the current passes from chromium to platinum, or if the cell is broken down by the application of more than 75 volts, it is an asymmetrical resistance when platinum is the anode, whilst if chromium is the anode the current passes freely; again, if too high an e.m.f. be applied to the platinum anode, another reversal occurs, and about 75 volts can again be stopped using chromium as anode. The chromium cell can also be used for the **rectification of alternating currents.** The phenomenon is attributed to the formation of a resistant film as in the case of the aluminium cell. W. Günther-Schulze studied the attraction of electrons for the CrO_4-ions. H. Nagaoka and T. Futagama studied the spluttering of chromium by the disruptive discharge in a magnetic field.

W. Ostwald found that when active chromium acts on acids, there is a **periodicity** in the rate of evolution of hydrogen. A piece of passive chromium rendered active by contact with cadmium under acid, was dissolved in 2N-HCl. The curve showing the rate of action is irregular for about 15 minutes, when it becomes periodic, the velocity rapidly increasing to a maximum and then falling more slowly to a minimum. The duration of each period increases during the progress of the reaction. Different forms of curve were obtained from different pieces of chromium; and two pieces placed in the same acid were found to give a double summation curve showing that the periodicity lies in the metal and not in the acid. An increase in the concentration of the acid causes an increase in the frequency of the periodic phenomena; the frequency is doubled by a rise of about 10°; the frequency is increased by the addition of oxidizing agents—*e.g.* nitric acid, nitrogen oxide, and chloric and bromic acids—and it is decreased by small amounts of formaldehyde or potassium cyanide. Dextrin and other carbohydrates help to bring about regular periodicity. No periodic phenomena were observed with the dissolution of iron, zinc, or manganese. The metal contained silicon, iron, sulphur, and carbon; but which of these is the active agent was not determined—purified chromium did not exhibit the phenomenon.

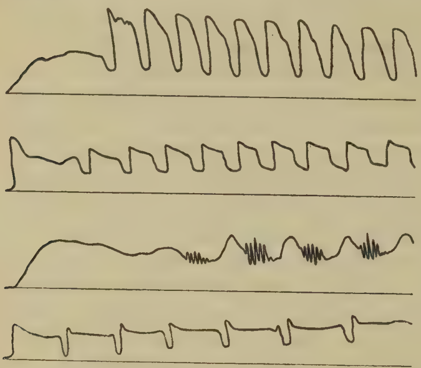

FIG. 5.—Periodic Evolution of Gas in the Dissolution of Chromium in Acids.

Nugatory attempts to render the metal active by the addition of cupric chloride, sodium sulphite, alcohol, ferrous chloride, ferric chloride, colloidal platinum, chromic acid, potassium nitrite; prolonged contact with metallic platinum; variation of temp. between 0° and 50°; previous treatment of the metal with chromic acid or potassium permanganate; fusion with potassium nitrate; heating on charcoal with sodium phosphate to give the metal a phosphorus content; melting in the electric oven in an atm. of coal-gas; using the metal as anode have all been made.

E. Brauer observed that the active chromium dissolving not only exhibits changes in its rate of evolution of hydrogen, but it also shows changes in its electric potential for the current produced by a cell of active chromium and platinum immersed in acid also varies periodically. The two sets of curves were analogous, but in some cases there is a variation in the electric properties when the evolution of hydrogen is apparently constant. The frequency increases with increasing conc. of acid, and is no longer apparent when the conc. of the acid is great enough. In one case, no periodicity was observed at 6°, periodicity was marked at 20°, and very pronounced at 31°. A piece of inactive chromium became active when rubbed with a piece of cadmium; and a slight activity was induced by the addition of arsenic or arsenic sulphides to the acid. E. Brauer attributes the periodicity to variations in the e.m.f. associated with the different oxidation stages of chromium. E. S. Hedges and J. E. Myers found that the addition of litharge would make chromium show the periodic phenomenon; they also showed that the periodic phenomenon is not due to the supersaturation of soln. or metal with gas; but is rather connected with the chemical change itself. The periodicity was shown to depend on the presence of a suitable catalytic agent and to be independent of the dissolving metal. The phenomenon was studied by B. Strauss and J. Hinnüber. W. Ogawa studied the action of chromium salts on galena as a radio-detector.

According to M. Faraday,[11] chromium is non-magnetic; this was not the conclusion of W. F. Barrett, but F. Wöhler, E. Glatzel, and H. Moissan found that the purified metal is non-magnetic. S. Curie studied the magnetization of iron with 2·5 to 3·4 per cent. of chromium; and K. Honda, of chromium with 20 per cent. of iron. M. Owen gave for the **magnetic susceptibility** of chromium $3{\cdot}16\times10^{-6}$ mass units; K. Ihde, 26×10^{-6} vol. unit; and K. Honda, $3{\cdot}7\times10^{-6}$ mass unit at 18°, and $4{\cdot}2\times10^{-6}$ mass units at 1100°. J. Weiss and H. K. Onnes found that at —25·9°, the magnetic properties of chromium are very feeble. E. Wiedemann found that the atomic magnetism of chromium in various salt soln. approximates 42 when that of iron in ferric chloride is 100. This result is independent of the nature of the anion associated with the chromium. W. Lepke found that with a field strength of *H* kgrms., the magnetic susceptibilities $\times 10^{-6}$ mass unit of massive and powdered chromium, are :

H .	1·0	3·3	7·0	10·0	16·0	18·0
Mass.	4·1	3·6	3·5	3·5	3·5	3·5
Powd.	4·3	5·4	4·2	4·1	4·0	3·9

P. Weiss and P. Collet calculated $63·3 \times 10^{-6}$ for the atomic permeability. J. Safranek found the magnetic susceptibility of chromium to be independent of the magnetic field between 2000 and 14,000 gauss and of the temp. between 100° and 600° and to have a value of $4·31 \times 10^{-6}$. The reciprocal of the susceptibility of the alloys plotted against temp. gives a straight line becoming concave towards the temp. axis at higher temp. The various magnetic constants are linear functions of the composition. P. S. Epstein found that the magnetic susceptibility of bivalent chromium is $7·9 \times 10^{-4}$ per unit mass ; and of tervalent chromium, $5·0 \times 10^{-4}$. Observations on the magnetic properties of chromium were also made by E. Wedekind, D. M. Bose, A. Dauvillier, R. H. Weber, and E. Feytis. P. Kapitza's observations on the effect of strong magnetic fields on the conductivity are summarized in Fig. 6. L. Rosenfeld discussed the relation between the magnetic susceptibility and the refractive index ; and E. C. Stoner, the magnetic moment. P. Weiss, and L. A. Welo studied the magnetism of chromium salts.

§ 5. The Chemical Properties of Chromium

H. Moissan[1] studied the chemical affinity of chromium and the iron family of elements. F. Fischer and F. Schrötter observed no reaction when chromium is sparked beneath liquid **argon.** H. R. Carveth and B. E. Curry found that electro-deposited chromium can occlude about 250 times its vol. of hydrogen; in one experiment 24·6 c.c. of the gas were obtained from 0·698 c.c. of metal. E. Martin measured the occlusion of hydrogen by chromium. According to G. F. Hüttig and F. W. Brodkorb, electrolytic chromium deposited at —50° may contain 0·45 per cent. of hydrogen, in supersaturated solid soln. At the ordinary temp., the hydrogen press. of this chromium is less than 1·0 mm., but at 58° a sudden evolution of hydrogen takes place, although a temp. of 350° is required in order to remove the whole of the gas. No reproducible relations between temp., press., and hydrogen conc. could be established. T. Weichselfelder and B. Thiede obtained **chromium trihydride,** CrH_3, as a black precipitate, by the action of hydrogen on an ethereal soln. of phenylmagnesium bromide, C_6H_5MgBr, in which the dry metal chloride is suspended. The sp. gr. is 6·77. W. Biltz discussed the mol. vol. According to H. Gruber, a sheet of electrolytically-deposited chromium will slowly evolve occluded hydrogen if placed in boiling water, and if held in a Bunsen flame it will appear to take fire and burn on the surface with a pale blue non-luminous flame, although the metal remains sufficiently cool to avoid being oxidized. A. Sieverts and A. Gotta studied this subject. The heat of formation of chromium hydride is 3800 cals. per mol. of hydrogen; and the sp. gr. is 6·7663 to 6·7708.

A. L. Bernoulli said that chromium absorbs oxygen from **air** and so acquires the surface film of oxide. The behaviour of chromium in air depends on its state of subdivision; there is pyrophoric chromium; the specimen obtained by L. N. Vauquelin slowly oxidized when heated in air; that obtained by A. Binet du Jassonneix glowed like tinder in **oxygen** at 300°; that obtained by F. Wöhler when heated in air became yellow, then blue, and finally acquired a crust of green chromic oxide; and that obtained by H. Moissan was unaltered by exposure to dry air, but in moist air the well-polished surface acquired a slight tarnish, owing to the formation of a superficial film which does not penetrate deeper into the metal. This subject was discussed by N. B. Pilling and R. E. Bedworth. H. P. Walmsley examined the nature of the sesquioxide obtained as smoke from the chromium arc. Unlike molybdenum, chromium was found by C. Matignon and G. Desplantes not to be oxidized when the finely-divided metal is shaken up with aq. ammonia in air. When heated by the tip of the oxyhydrogen blowpipe flame, chromium burns yielding brilliant sparks; and when heated to 2000° in oxygen, it burns with the production of numerous sparks, more brilliant than those of iron. N. B. Pilling and R. E. Bedworth studied the rate of oxidation of chromium. F. Wöhler observed that chromium gives sparks and burns to chromic oxide when heated by the flame of a spirit-lamp fed with oxygen. H. W. Underwood described the use of chromium as an oxidation catalyst. H. V. Regnault, and F. Wöhler found that it decomposes when heated to bright redness in the vapour of **water,** forming hydrogen, and chromic oxide; and J. J. Berzelius found that the metal is not oxidized by boiling water. The action of **hydrogen dioxide** was found by L. J. Thénard to be at first feeble but later more vigorous. Part of the oxygen is given off free, and part combines with the metal. W. Guertler and T. Liepus observed no reaction by 48 hrs.' exposure to sea-water, aerated sea-water, or aerated rain-water. W. G. Mixter observed that no perchromate is formed by the action of **sodium dioxide** on chromium.

According to F. Wöhler, chromium glows when heated in **chlorine,** forming violet chromic chloride; and H. Moissan said that the reaction occurs at 600°. The red-hot metal is also attacked by **bromine** vapour—*vide infra,* chromic bromide; and with **iodine** vapour. W. Hittorf observed that chlorine and bromine make chromium passive, while R. Hanslian found that the presence of chromium does not affect the f.p. or b.p. of iodine. G. Tammann studied the action of iodine vapour on chromium. W. Guertler and T. Liepus observed no reaction with 48 hrs.' exposure to sat. chlorine-water. C. Poulenc found that **hydrogen fluoride** converts the red-hot metal into chromous fluoride; and C. E. Ufer observed that with **hydrogen chloride,** chromous chloride is formed. J. J. Berzelius found that the metal dissolves in **hydrofluoric acid,** particularly when warm, and hydrogen is given off. F. Wöhler, E. Jäger and G. Krüss, J. J. Berzelius, H. St. C. Deville, etc., noted that the metal dissolves in **hydrochloric acid** with the evolution of hydrogen and the formation of chromous chloride. W. Guertler and T. Liepus observed no reaction in less than 8 hrs. with 10 and 36 per cent. hydrochloric acid—*vide supra,* the passive state. H. Moissan said that hydrochloric acid attacks the metal slowly in the cold, and rapidly when heated, while the dil. acid has no action at ordinary temp., but on boiling, the attack is vigorous. W. Rohn found that 10 per cent. hydrochloric acid dissolves 77·4 grms. per sq. dm. per hr. during 24 hrs. in the cold and 150 grms. per sq. dm. per hr. when hot; and D. F. McFarland and O. E. Harder, that the normal acid dissolves 16,976·4 mgrms. per week per sq. in. W. Hittorf observed that chromium dissolves in hydrofluoric and hydrochloric acids as well as in **hydrobromic acid and hydriodic acid,** forming chromous salts and hydrogen. T. Döring said that the less pure the chromium prepared by the alumino-thermite process, the more quickly is it dissolved by the halide acid. The chromous chloride formed by the soln. of chromium in hydrochloric acid is converted, by a secondary reaction, into chromic chloride, the change being complete if the reaction is carried out at the ordinary temp., but less than complete if at 100°. This change is ascribed to a catalytic action of silica. If air is excluded, chromous chloride is stable in neutral soln., but in hydrochloric acid soln. it has a tendency to form chromic chloride; the reaction, which is accompanied by evolution of hydrogen, is extremely slow, but is markedly accelerated by addition of platinum black, finely-divided gold, or silica. The formation of chromic chloride from chromous chloride in acid soln. takes place according to the equation: $2CrCl_2+2HCl\rightleftharpoons2CrCl_3+H_2$, and is a reversible reaction. W. Hittorf found that chromium becomes passive in **chloric acid,** and in **perchloric acid.**

H. Moissan observed that chromium filings become incandescent if heated to 700° in **sulphur** vapour, and chromium sulphide is formed; and when heated to 1200° in a current of **hydrogen sulphide,** crystals of chromium sulphide are formed. W. Guertler and T. Liepus observed no reaction with 48 hrs.' exposure to 10 and 50 per cent. soln. of **sodium sulphide** with or without the addition of alkali-lye. N. Domanicky found that chromium is not readily attacked by an ethereal soln. of **sulphur monochloride;** and E. H. Harvey, that it is not attacked in a year at room temp. J. Férée said that pyrophoric chromium unites with **sulphur dioxide** with incandescence. H. V. Regnault, E. M. Péligot, H. Moissan, W. Hittorf, F. Wöhler, and E. Jäger and G. Krüss noted that chromium is but slowly attacked by dil. **sulphuric acid** in the cold, the action is slow even when hot, hydrogen is given off, and, if the action takes place out of contact with air, blue crystals of chromous sulphate can be obtained from the soln. Boiling, conc. sulphuric acid with chromium gives off sulphur dioxide. W. Guertler and T. Liepus observed no action in 48 hrs. with 10 per cent. H_2SO_4 and with 20 per cent. H_2SO_4 sat. with sodium sulphate. W. Rohn found that 10 per cent. sulphuric acid dissolves 0·01 grm. per sq. dm. per 24 hrs. in the cold, and 45 grms. per sq. dm. per hr. when hot; and D. F. McFarland and O. E. Harder, that the normal acid dissolves 1·00 mgrm. per sq. in. per week. J. Voisin, and A. Burger studied the action of sulphuric acid on the metal. G. Walpert observed that the rate of dissolution and the electrode potential of chromium in $4N$-H_2SO_4—unlike the case with iron (*q.v.*)—is raised by the addition of small proportions of potassium or sodium chloride, bromide, and iodide, and the period of induction is shortened. The addition of larger proportions of these salts may act in the reverse way. Gelatin reduces the rate of dissolution of chromium in the acid; additions of acetic acid act similarly. E. Beutel and A. Kutzelnigg studied the films produced by a boiling soln. of **sodium thiosulphate** and lead acetate. M. G. Levi and co-workers found that a soln. of **potassium persulphate** rapidly dissolves chromium as chromic acid, and a little gas is evolved; the process of dissolution is slow with a soln. of **ammonium persulphate.**

A. Binet du Jassonneix, I. Zschukoff, and J. Férée found when pyrophoric chromium unites with **nitrogen,** a bronze-coloured nitride is formed. F. Adcock found that molten chromium rapidly absorbs nitrogen up to the extent of 3·9 per cent., and G. Valensi, and R. Blix also obtained evidence of the formation of a nitride when nitrogen is absorbed by chromium at an elevated temp. E. Martin studied the occlusion of nitrogen and the formation of nitrides by chromium; G. Tammann suggested complexes are formed under these conditions rather than ordinary compounds—*e.g.* $Cr_4(N_2)$, and $Cr_2(N_2)$. G. G. Henderson and J. C. Gallety observed that at 850° **ammonia** reacts with chromium forming the nitride. W. Guertler and T. Liepus observed that no reaction with 10, 50, and 70 per cent. ammonia soln. occurs in 48 hrs.; and D. F. McFarland and O. E. Harder, that a normal soln. dissolves 1·60 mgrms. per sq. in. per week. F. W. Bergstrom found that **potassamide** in liquid ammonia soln. acts very slowly or not at all on chromium. J. Férée, and F. Emich said that at ordinary temp. pyrophoric chromium unites with **nitric oxide** with incandescence forming a mixture of chromium oxide and nitride. E. Müller and H. Barck observed that nitric oxide has no action on chromium at 600°. A. L. Bernoulli said that nitric oxide is absorbed by chromium, and when the metal is treated with **nitric acid,** and thoroughly washed, it liberates a measurable amount of nitric oxide when allowed to remain in water for several hrs.—active chromium does not yield the gas under similar conditions. W. Rohn found that 10 per cent. nitric acid dissolves 0·013 grm. per sq. dm. per 24 hrs. in the cold, and none in an hour when hot; W. Guertler and T. Liepus observed no action in 48 hrs. with 10 and 50 per cent. nitric acid, or with aqua regia; and D. F. McFarland and O. E. Harder found that normal nitric acid dissolves 0·35 mgrm. per sq. in. per week. W. Hittorf said that nitric acid makes chromium passive. F. Wöhler, E. Jäger and G. Krüss, H. St. C. Deville, and C. C. Palit and N. R. Dhar said that dil. or conc. nitric acid does not act on chromium. H. Moissan said that chromium is very slowly attacked by dil. nitric acid; and that fuming nitric acid, as well as aqua regia, have no action on the metal. E. Frémy, and J. J. Berzelius also noted the resistance the metal offers to attack by aqua regia. A. Granger observed that chromium is attacked by **phosphorus** at 900°. W. Hittorf found that **phosphoric acid** makes chromium passive. W. Rohn found that 10 per cent. phosphoric acid dissolves no chromium in 24 hrs. when cold, or in an hour when hot. He also found that 10 per cent. **acetic acid** dissolves 0·13 grm. per sq. dm. per 24 hrs. in the cold, and 0·03 grm. per sq. dm. per hr. when hot.

According to H. Moissan, chromium reacts with **carbon** when strongly heated, forming a carbide; the chromium also undergoes a process of concentration as in the case of iron. The reaction between carbon and chromium was studied by K. Nischk, R. Kraiczek and F. Sauerwald, and E. Tiede and E. Birnbräuer. G. Charpy said that **carbon monoxide** reacts with chromium at 1000°, forming a mixture of carbon and chromic oxide. H. Moissan also found that at 1200° a mixture of carbon monoxide and **carbon dioxide** attacks chromium superficially, and the metal acquires a crust of chromic oxide mixed with carbon. Hence, the impossibility of obtaining chromium free from carbon in an ordinary metallurgical furnace, even when using crucibles of quicklime. Chromium is oxidized when heated in carbon monoxide. S. Medsforth studied the promotor action of chromium on nickel as catalyst in the hydrogenation of carbon monoxide or dioxide. W. Guertler and T. Liepus observed no action after 4 weeks' exposure to water sat. with carbon dioxide. W. Hittorf said that **citric acid** makes chromium passive; and a similar result was obtained with **formic, acetic, and tartaric acids.** S. Hakomori studied the action of chromium on ammonia in the presence of tartaric acid and glycerol. J. H. Mathews observed that a soln. of **trichloractic acid** in nitrobenzene does not attack chromium. W. Guertler and T. Liepus observed no reaction with citric and tartaric acids during 24 hrs.' exposure. D. F. McFarland and O. E. Harder observed that fatty acids dissolved 1·23 mgrms. per sq. in. per week; and C. B. Gates, that chromium is not attacked by **oleic acid** at room temp. J. G. Thompson and co-workers studied the action of soln. of **urea,** and of **ammonium carbonate** on the metal. H. S. Taylor and G. B. Kistiakowsky discussed chromic oxide as a methanol catalyst; and O. Schmidt as a hydrogenation catalyst. H. Moissan found that when heated in an electric furnace chromium readily unites with **silicon,** forming a silicide; and with **boron,** forming a boride. E. Vigouroux found that at 1200° chromium reacts with **silicon tetrachloride,** forming a silicide; and, according to W. Treitschke and G. Tammann, it attacks **porcelain** vigorously at 1600°.

A. Burger said that the vapour of **calcium** has no appreciable action on chromium at a red-heat. W. G. Imhoff found that chromium resists attack by molten **zinc** more readily than does iron or steel. W. Treitschke and G. Tammann found that the action on **magnesia** at 1700° is quite small. H. Moissan said that fused **potassium hydroxide** has no appreciable action on chromium at dull redness; but J. J. Berzelius said that at a red-heat, in air, the chromium is attacked. W. Guertler and T. Liepus observed no reaction with 10 and 50 per cent. soln. of **sodium hydroxide** during 8 hrs.' exposure. M. Leblanc and O. Weyl found that potassium hydroxide between 550° and 660° has a slight action on chromium, forming traces of potassium and hydrogen. D. F. McFarland and O. E. Harder observed that normal sodium hydroxide dissolves 0·35 mgrm. per sq. in. per week, and normal **sodium chloride,** 2·00 mgrms. per sq. in. per week. U. Sborgi and G. Cappon found that in a soln. of **calcium and ammonium nitrate** in ethyl alcohol, chromium is passive with low current pressures, and with high pressures, chromous ions are formed. J. J. Berzelius, F. Wöhler, and H. Moissan observed that chromium is energetically attacked by fused **potassium nitrate** at a dull red-heat; and that the attack by fused **potassium chlorate** is even more vigorous—the chromium floats on the chlorate producing vivid incandescence. H. Moissan said that chromium is slowly attacked by **mercuric chloride;** W. Guertler and T. Liepus observed a slight action with a 1 : 500 soln. at 90°; and no action with **magnesium chloride** soln.

Some reactions of analytical interest.—Chromic salts give no precipitate with **hydrochloric acid;** and **hydrogen sulphide** gives no precipitate in acidic soln., but in alkaline soln. **ammonium sulphide** precipitates chromic hydroxide; and a similar precipitate is obtained with **ammonia.** According to F. Jackson,[2] the reaction with ammonia is sensitive to 1 : 4000; and with ammonium sulphide to 1 : 8000. The chromic hydroxide is slightly soluble in an excess of ammonia forming a violet soln. The precipitation should be made from a boiling soln. using as little ammonia as possible. Aq. soln. of the **alkali hydroxides** also precipitate chromic hydroxide, and with an excess of the alkali, some chromium passes into soln.: $3KOH+Cr(OH)_3\rightleftharpoons 3H_2O+Cr(OK)_3$, an excess of water or boiling makes the reaction pass from right to left, and unlike the corresponding case with aluminium, nearly all the chromium is precipitated as hydroxide. **Alkali carbonates** also precipitate chromic hydroxide; and similarly J. N. von Fuchs found that **calcium carbonate** precipitates a green chromic carbonate; and H. Demarçay obtained a similar result with **strontium, barium, and magnesium carbonates.** H. Rose said that with cold soln. barium carbonate slowly precipitates green hydrated chromic oxide. A boiling soln. treated with **sodium thiosulphate** gives a precipitate of chromic hydroxide. With **alkali phosphates,** a green precipitate of chromic phosphate is formed; this is soluble in mineral acids and in cold acetic acid; when the acetic acid soln. is boiled, chromic phosphate is again precipitated. **Alkali acetates** give no precipitate with cold or boiling soln., but if aluminium and ferric salts are present in excess, basic acetate is precipitated; if the chromic salt be in excess, the precipitation is incomplete. **Peroxides**—*e.g.* hydrogen, sodium or lead dioxide—and **per-salts**—*e.g.* persulphates, perborates, and percarbonates—convert alkaline soln. into yellow chromates; similarly, **potassium permanganate** in hot, alkaline soln. converts the chromic salt into a chromate. When chromic oxide or hydroxide is fused with alkalies and other bases, in air, chromate is formed.

A yellow soln. of the chromate becomes orange coloured when treated with dil. **sulphuric acid;** and with conc. sulphuric acid, red needles of chromic acid may be formed, and the soln. may become green with the evolution of oxygen: $2CrO_3+3H_2SO_4=3H_2O+3O+Cr_2(SO_4)_3$. In neutral soln., **silver nitrate** gives a brownish-red precipitate soluble in ammonia and mineral acids; with conc. soln. of potassium dichromate, silver nitrate may precipitate reddish-brown silver dichromate which when boiled with water forms a soln. of chromic acid, and normal silver chromate. With **lead acetate,** lead chromate is precipitated; the precipitation is incomplete with lead nitrate unless the soln. contains acetates. According to P. Harting, a precipitate is obtained with lead salts and potassium dichromate and the reaction is sensitive to 1 : 111,982; T. G. Wormley gave 1 : 107,700; and F. Jackson, to 1 : 32,000. Neutral chromates give yellow barium chromate when treated with **barium chloride;** the precipitate is soluble in mineral acids, and insoluble in acetic acid. If dichromates are used the precipitation is incomplete except in the presence of alkali acetates. According to F. Jackson, the reaction with barium salt and potassium dichromate is sensitive to 1 : 256,000. A cold soln. of a chromate gives brown mercurous chromate when treated with **mercurous nitrate;** and if the soln. is boiled, fiery-red, normal mercurous chromate is formed. **Reducing agents**—*e.g.* hydrogen sulphide, sulphur dioxide, etc.—convert the chromates into green chromic salts. According to P. Cazeneuve,[3] N. M. Stover, and A. Moulin, chromates give a purple, violet, red or brown coloration with **diphenylcarbazide,** or the acetate, in alcoholic soln. According to K. Pander, and J. Froidevaux, **guaiacum tincture** gives an evanescent, blue coloration with chromates. J. Meyerfeld obtained a yellowish-red coloration with an aq. soln. of **pyrogallol dimethyl ether;** and P. N. van Eck obtained a blue coloration with an aq. soln. of **α-naphthylamine** and tartaric acid; D. Lindo, a brown band with **phenol,** and a rainbow band with **orcinol;** P. König obtained a red or violet coloration with **1 : 8 dihydroxynaphthalene-3 : 6-disulphonate**—it is said to be sensitive to 0·0000008 grm. of chromium in 10 c.c. L. C. A. Barreswil found that if an acidic soln. of a chromate be treated with **hydrogen dioxide** and then shaken with ether, the upper ethereal layer will be coloured blue—*vide infra,* perchromates. S. N. Chakrabarty and S. Dutt studied organic syntheses with chromium powder.

The physiological action of chromium salts.—According to G. C. Gmelin,[4] chromic chloride is less active than normal potassium chromate; 1·9 grms. of the latter killed a rabbit within 2 hrs., while 3 grms. of the chloride had no action. Subcutaneous injections of 0·2 to 0·4 grm. of potassium chromate were found by E. Gergens, and C. Posner to act with great intensity on rabbits, and death often occurred within a few hours. E. V. Pelikan found that 0·06 to 0·36 grm. of potassium dichromate is fatal to rabbits and dogs. Workmen exposed to the dust of potassium dichromate were stated by B. W. Richardson to acquire a bitter disagreeable taste in the mouth with an increase of saliva which helps to get rid of most of the poison, and little ill-effects are observed. Those who inspire by the nose suffer from inflammation of the septum, which gradually gets thin, then ulcerated, and finally the whole septum is destroyed. The dichromate also causes painful skin eruptions, and ulcerations which the workmen call *chrome holes.* These skin diseases start from an excoriation; so long as the skin remains whole, there is little local effect.

Horses, also, about the works develop ulcerations if the salt get into wounds or cracks in the legs; and the animals may lose their hoofs. Cases of poisoning by chromates are rare. They have been recorded by J. Maschka, E. O. MacNiven, W. A. McLachlan, J. J. Bloomfield and W. Blum, A. M'Crorie, G. Wilson, J. T. Gadsby, A. D. Walker, G. Leopold, O. von Linstow, and R. C. Smith. The symptoms are severe gastro-intestinal inflammation, accompanied by depression, stupor, and death. The subject was discussed by A. Hébert, H. Becker, L. Lewin, etc. The objectionable uses of chromates for preserving milk, etc., was discussed by G. Denigès,[5] and J. Froidevaux; the antiseptic action of chromates by A. Müller, P. Miquel, C. Chamberland and E. Roux, P. J. Laujorrois, J. F. Clark, C. H. Pander, A. Strubell, H. Schulz, H. Coupin, etc. M. E. Pozzi-Escot found that chromic salts are less poisonous than potassium chromate and dichromate, chrome-alum or chromic acid towards the lower fungi—*e.g. saccharomycetes*. P. König found that with certain minute concentrations plant life may be stimulated by chromium salts and chromates; the toxic action is greater the higher the degree of oxidation of the chromium. A wheat plant was killed by a 0·0064 per cent. soln. of sodium dichromate, and a 0·5 per cent. soln. of chrome-alum was needed to produce a similar result. T. Pfeiffer and co-workers could not find any beneficial stimulating effect of chromite, or of potassium dichromate on the growth of oats and barley.

Some uses of chromium.—One of the most important applications of chromium is in the production of various alloys,[6] principally ferrochromium alloys for the manufacture of special steels many of which contain about 2 per cent. of chromium and a small proportion of other metals—*vide* the alloys of iron. The chrome-alloy steels are hard and tough. They are used in making armour-plate, armour-piercing projectiles, burglar-proof safes; tyres, axles, springs for railways and motor-cars, stamp-mill shoes, crusher jaws, the so-called rustless cutlery, *stellite*—an alloy containing chromium, cobalt, and molybdenum and tungsten—for high speed tools which retain their cutting edge at temp. approaching redness; *nichrome*—nickel, chromium, iron (60 : 14 : 15), a high temp. resistance alloy; chromium-vanadium steel; chromium magnet steel; heat-resisting and acid-resisting steels; etc. Chromium plating as a protective coating for steel is much employed [7]—*vide supra*, the electrodeposition of chromium. Perhaps the largest demand for chromium is in the form of chromite used as a refractory in certain parts of open-hearth and other furnaces.[8] Chromium compounds are used in tanning certain leathers—chrome leathers; as a mordant for dyeing; it is used for impregnating wood, paper, etc., with chromic hydroxide; and in the preparation of filaments for incandescent lamps. Chromates are used for making gelatine insoluble—for a mixture of gelatine and potassium dichromate becomes insoluble when exposed to light—in colour printing, block printing, heliography, photolithography, photozincography, etc. Chromium compounds are used in making safety matches; as antiseptics; in bleaching oils; in the purification of wood vinegar; as a component of certain galvanic cells; an oxidation agent in the preparation of some aniline dyes and in a number of analytical and chemical processes; as a catalytic agent in the preparation of sulphur trioxide (*q.v.*), and, according to H. W. Underwood,[9] in the hydrogenation of organic compounds.

Chromic oxide is employed as green pigments for paints—chrome-green, emerald-green, Cassal's green, etc.—and it may be associated with other substances—*e.g.* boric oxide, phosphoric oxide, zinc oxide, etc. to produce special tints, there are yellow chromates of lead, etc.—*e.g.* chrome yellow, lemon yellow, Paris yellow, royal yellow, etc.; red basic lead chromates—*e.g.* chrome-orange, chrome-vermilion, etc.; and brown, manganese chromate.[10] Chromic oxide is employed in producing on-, in-, and underglaze green colours in enamel, pottery and glass manufacture; on-glaze yellows employed for on-glaze work, and in enamelling are derived from lead chromate, the on-glaze reds and orange colours, from basic lead chromate. A crimson or pink colour for pottery decoration is based on the result of calcining stannic oxide with one or two per cent. of chromic oxide; for the coloration of alumina with chromium to form artificial rubies—*vide* alumina. C. J. Smithells[11] described the manufacture of articles from chromium.

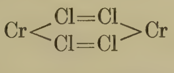
§ 6. The Atomic Weight and Valency of Chromium

In 1818, J. J. Berzelius[1] represented chromic anhydride by the formula CrO_6 but later gave CrO_3, and the corresponding formula for chromic oxide became Cr_2O_3 by analogy with the sesquioxides of aluminium, iron and manganese. This made the at. wt. of chromium approximate to 52, and is in agreement with the tervalency of chromium in this oxide, and also with the sp. ht. rule ; with the isomorphism of the chromous and ferrous salts observed by C. Laurent ; the isomorphic replacement of chromic, ferric, and aluminium hydroxides in the silicate minerals, spinels and chromites, alums, and complex cyanides ; and the isomorphism of chromates and sulphates—*vide supra*. The at. wt. 52 also agrees with the electrolysis of chromium salts which is in accord with Faraday's law ; with the recognized position of chromium in the periodic table ; and with the frequency of the X-rays observed by H. G. J. Moseley, and M. Siegbahn and W. Stenström.

Chromium under different conditions may act as a bi-, ter-, and sexi-valent element. F. Pintus discussed the possibility of the formation of compounds with *univalent* chromium in such reactions as : $4CrCl_2+4C_6H_5MgBr=(C_6H_5)_4CrCl+3CrCl\ 2MgCl_2+2MgBr_2$. *Bivalent* chromium in the dichloride has a vap. density at 1600° half as much again too high for the simple molecule $CrCl_2$, and, according to L. F. Nilson and O. Pettersson, the chromium is really tervalent $Cr_2{=}Cr{-}Cr{=}Cl_2$; but it may be



$$Cr{<}\begin{smallmatrix}Cl=Cl\\Cl=Cl\end{smallmatrix}{>}Cr$$

The isomorphism between $CrSO_4.7H_2O$, and $FeSO_4.7H_2O$, indicated by C. Laurent, shows that the bivalency of chromous chromium corresponds with the bivalency of ferrous iron. The *tervalency* of chromium has been more definitely established by L. F. Nilson and O. Pettersson's observations on the vap. density of chromic chloride ; F. Hein and E. Markert's observations on triphenyl chromium, $Cr(C_6H_5)_3$; and G. Urbain and A. Debierne's observations on the vap. density of chromic acetylacetonate. There is also the isomorphism of chromium with tervalent aluminium in the alums. W. Just, W. Eissner, E. Markert, and F. Hein and co-workers also prepared tetraphenyl chromium, $Cr(C_6H_5)_4$, in which the metal is presumably *quadrivalent ;* and possibly *quinquevalent* in the compounds of the type $Cr(C_6H_5)_4OH$. The *sexivalency* of chromium is indicated by F. Hein's observations on the vap. density of chromyl chloride ; and by the relations between sulphur trioxide, SO_3, and chromic trioxide, CrO_3, as illustrated by the isomorphism of the sulphates and chromates observed by E. Mitscherlich, F. Mylius and R. Funk, and H. Salkowsky. Of course, chromium, in chromic anhydride, may be bi- or quadri-valent

Bivalent.

Quadrivalent.

Sexivalent.

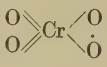
and W. Manchot believed that the chromium is quadri- not sexi-valent, and similarly also with the other cases of sexivalent chromium ; hence, the whole force of the argument turns on the analogy with what he assumed to be sexivalent sulphur. W. Manchot and R. Kraus reported chromium dioxide, CrO_2, in which the chromium is bi-, ter-, or quadrivalent

Bivalent.

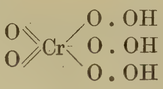
O=Cr–O–O–Cr=O
Tervalent.

Quadrivalent.

and W. Manchot believed it to be *quadrivalent.* The isomorphism of the complex salts of chromium oxytrichloride, $CrOCl_3$, say $CrOCl_3.2CsCl$ with $CbOCl_3.2CsCl$, observed by R. F. Weinland and co-workers, agrees with the assumption that chromium is here quinquevalent. F. Olsson obtained addition products of quinquevalent chromium. R. Luther and T. F. Rutter also assumed that in the reaction between hydriodic acid and chromic acid, the chromium is first reduced to a quinquevalent stage and then to a quadrivalent stage. According to E. H. Riesenfeld, chromium in chromium tetroxide, CrO_4, is sexivalent, and in the perchromate H_3CrO_8, *septivalent :*



CrO_4



H_3CrO_8

A. Werner,[2] and P. Pfeiffer and co-workers described optically active chromic diaquodiethylenediamine salts, $[Cren_2(H_2O)_2]X_3$; chromic hydroxyaquodiethylenediamine salts, $[Cren_2(OH)(H_2O)]X_2$; A. Werner, and P. Pfeiffer and co-workers, chromic dichlorodiethylenediamine salts, $[Cren_2Cl_2]X$; chromic dibromodiethylenediamine salts, $[Cren_2Br_2]X$; and chromic dithiocyanatodiethylenediamine salts, $[Cren_2(SCy)_2]X$.

J. J. Berzelius [3] made the first serious determination of the at. wt. of chromium ; he precipitated lead nitrate with an alkali chromate, and weighed the resulting lead chromate. His results for the at. wt. gave 56 from the ratio $Pb(NO_3)_2 : PbCrO_4$; and 54 from $BaCrO_4 : BaSO_4$. Later observers have shown that the method is unreliable—with conc. soln., the precipitate adsorbs alkaline salts, and with dil. soln., the precipitation is incomplete. E. M. Péligot analyzed chromous acetate and chromium chloride, and obtained a value for the at. wt. 52·5, much lower than that of J. J. Berzelius ; and V. A. Jacquelain obtained a very low result, 50·1. In neither case were sufficient data described in the reports to enable estimates to be made of the value of the work. Some general observations on the subject were made by W. A. Noyes, and S. Lupton.

In 1846, N. J. Berlin obtained 52·6 to 52·9 from the ratio $2AgCl : Ag_2CrO_4$; 52·3 to 52·5 from $Cr_2O_3 : 2Ag_2CrO_4$; 52·6 from $2AgCl : Ag_2Cr_2O_7$; 52·3 from $Cr_2O_3 : Ag_2Cr_2O_7$; and 52·0 from $Pb(NO_3)_2 : PbCrO_4$. A. Moberg obtained 53·2 from the ratio $Cr_2O_3 : Cr_2(SO_4)_3$; 53·7 from $Cr_2O_3 : Cr_2(SO_4)_3$; and 53·6 from Cr_2O_3 : chrome-alum. J. Lefort calculated 53·1 from the ratio $BaCrO_4 : BaSO_4$; and R. Wildenstein, 53·6 from $BaCrO_4 : BaCl_2$. F. Kessler obtained 52·2 to 52·4 from the ratio $KClO_3 : K_2Cr_2O_7$; M. Siewert, 52·05, from $CrCl_3 : 3AgCl$; 52·1, from $Ag_2Cr_2O_7 : 2AgCl$; and 52·0, from $Ag_2Cr_2O_7 : Cr_2O_3$; H. Baubigny, 52·1 from $Cr_2(SO_4)_3 : Cr_2O_3$; S. G. Rawson, 52·2 from $(NH_4)_2Cr_2O_7 : Cr_2O_3$; F. W. Meinecke, 52·2, from $(NH_4)_2Cr_2O_7 : Cr_2O_3$; 52·08, from $4AgCl : Cr_2O_3$; 52·06, from $Ag_2CrO_4 : I_2$; 52·2, from $[Ag_2(NH_3)_4]CrO_4 : I_2$; 52·10, from $K_2Cr_2O_7 : KClO_3$; and 52·13, from $(NH_4)_2Cr_2O_7 : I_2$; F. G. Nunez, 52·025, from $CrCl_2O_2 : 2AgCl$; G. P. Baxter, E. Mueller and M. A. Hines, 52·005, from $2AgCl : Ag_2CrO_4$, and 52·012, from $2AgBr : Ag_2CrO_4$; and G. P. Baxter and R. H. Jesse, 52·016, from $2AgBr : Ag_2Cr_2O_7$. J. Meyer gave $52·01 \pm 0·01$ as the best representative value; F. W. Clarke, $52·0193 \pm 0·0013$; while the International Table for 1926 gave 52·01.

The **atomic number** of chromium is 24. F. W. Aston[4] found chromium has four **isotopes** with mass numbers and percentage abundance respectively 50 and 4·9; 52 and 81·6; 53 and 10·4; and 54 and 3·1, making the at. wt. 52·011. N. Bohr gave for the **electronic structure** (2) for the K-shell; (4, 4) for the L-shell; (4, 4, 4) for the M-shell; and (2) for the N-shell. Speculations on the subject were made by S. Meyer, R. H. Ghosh, H. Lessheim and co-workers, C. D. Niven, K. Höjendahl, R. G. W. Norrish, R. Samuel and E. Markowicz, D. M. Bose, F. Hund, I. Tamm, R. Ladenburg, A. S. Russell, P. Ray, J. D. M. Smith, J. N. Frers, O. Feussner, C. G. Bedreag, A. Sommerfeld, and N. Collins. Evidence of **atomic disintegration** by bombardment with α-rays was observed by H. Pettersson and G. Kirsch. The subject was discussed by G. I. Podrowsky.

§ 7. The Alloys of Chromium. Chromides

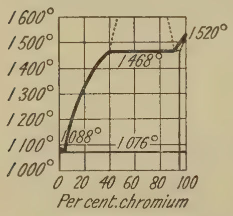

FIG. 7.—Freezing-point Curve of Cu–Cr Alloys.

G. Hindrichs[1] prepared **copper-chromium alloys** by the direct union of the elements. G. Hindrichs said that in the molten state the elements are only slightly soluble in one another; H. Moissan said that molten copper can take up 0·5 per cent. of chromium; and A. B. du Jassonneix that boiling copper can take up 1·6 per cent. of chromium. G. Hindrichs found that the emulsion formed by the two elements does not separate readily into two layers. E. Siedschlag's f.p. curve is shown in Fig. 7. E. Siedschlag found that there is only a partial miscibility in the liquid state with a eutectic at 1076° and 1·5 per cent. of copper. The limits within which a mixture of the two liquids is formed are 37 and 93 per cent. of chromium, above 1470°. Only heterogeneous mixtures of two kinds of crystals are obtained in the solid state, chromium, and a eutectic rich in copper. E. Placet, the Electrometallurgical Co., and D. S. Ashbrook deposited electrolytically a mixture of the two elements. The Neo-Métallurgie Marbeau, and L. P. Hamilton and E. F. Smith heated a mixture of chromium and copper oxides with carbon; P. L. Hulin reduced the mixed oxides with sodium; and H. Goldschmidt, with aluminium. G. Hindrichs reduced a mixture of chromic oxide, potassium dichromate, and cupric sulphide. H. Goldschmidt said that an alloy with 10 per cent. of chromium is greyish-red and harder than copper. L. P. Hamilton and E. F. Smith prepared a greyish-red alloy with 7 per cent. chromium and a sp. gr. 8·346. The Electrometallurgical Co. reported that chromium containing one-thousandth part of copper is harder and tougher than copper; alloys with 0·5 to 20 per cent. of chromium have approximately the toughness of steel, and they are very resistant towards acids, and alkalies, and they also resist high temp. M. G. Corson studied the hardness of the alloys. D. F. McFarland and O. E. Harder observed that the sp. gr. of the alloys with 91·68, 83·02, and 74·05 per cent. of copper were respectively 8·78, 8·60, and 8·47; and Brinell's hardness, respectively <68, 69, and 68. The corrosion of the alloys by normal hydrochloric, sulphuric, and nitric acids, normal soln. of sodium chloride, and hydroxide, ammonium hydroxide and fatty acids, expressed in terms of the loss in mgrms. per sq. in. per week, are indicated in Table II.

TABLE II.—THE CORROSION OF CHROMIUM-COPPER ALLOYS.

Copper (Per cent.).	NaOH.	HCl.	H_2SO_4.	HNO_3.	NaOH.	NH_4OH.	Fatty acids.
91·68	4·33	42·8	17·20	12·60	10·40	41·80	10·50
83·02	4·00	38·3	14·20	13·10	9·6	57·50	—
74·05	4·60	30·3	16·40	60·30	8·86	67·50	10·70

The **silver-chromium alloys** have not been closely studied. According to G. Hindrichs, liquid chromium and silver are only partially miscible; solid soln. are not formed. The addition of 5 per cent. of silver lowers the f.p. of chromium 50°. A reconstructed curve by G. Hindrichs is shown in Fig. 8. L. Jordan and co-workers measured the hardness, tensile strength, and elongation of these alloys. R. Vogel and E. Trilling's observations on the **gold-chromium alloys** are summarized in Fig. 9. No compounds of definite composition are formed. There are three kinds of mixed crystals, one rich in chromium, and two rich in gold. The Greek letters in Fig. 9 refer to the solid soln.

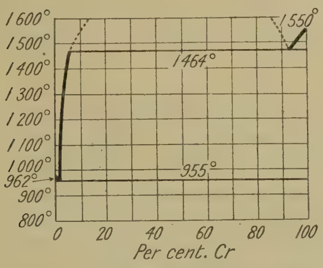

FIG. 8.—Freezing-point Curve of Ag–Cr Alloys.

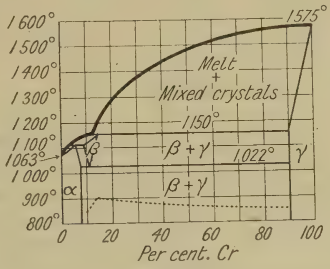

FIG. 9.—Freezing-point Curve of Au–Cr Alloys.

According to H. le Chatelier,[2] a **zinc-chromium alloy,** with 7 per cent. Cr, can be obtained by melting zinc mixed with alkali and chromic chloride. G. Hindrichs found that molten zinc dissolves a little chromium; an alloy with 5 per cent. of chromium had a break 10°–15° above the m.p., and an arrest near the m.p. of zinc. No **cadmium-chromium alloy** could be obtained by heating a mixture of the two elements for 6 hrs. at 650°.

A. S. Russell and co-workers [3] found chromium to be slightly soluble in mercury. G. Tammann and J. Hinnüber said that the solubility of chromium in mercury is $3 \cdot 1 \times 10^{-11}$ per cent. C. F. Schönbein, N. Bunge, Z. Roussin, and C. W. Vincent prepared a **mercury-chromium alloy** or **chromium amalgam,** by the action of potassium or sodium amalgam on a conc. soln. of chromic chloride; and H. Moissan obtained the amalgam by a similar process, as well as by the action of sodium amalgam on chromous chloride, bromide, or iodide. R. Myers obtained it by the electrolysis of a soln. of chromic sulphate in dil. sulphuric acid using a platinum anode, and mercury cathode; J. Férée found that with a soln. of chromic chloride the yield is poor. H. Moissan said that the amalgam is less fluid than mercury; and J. Férée, that it decomposes in air into chromous oxide and mercury. G. Tammann and J. Hinnüber obtained amalgams by reducing soln. of chromium sulphate with a mercury cathode. H. Moissan added that in air, the amalgam acquires a black film of oxide. It is slowly decomposed by dry air, and rapidly in moist air. R. Myers also found that it is rapidly decomposed by water. C. F. Schönbein observed that when the amalgam is shaken with water and air some hydrogen dioxide is formed; this reaction is favoured by dil. sulphuric acid. H. Moissan found that the amalgam is insoluble in boiling, conc. sulphuric acid, and that it is soluble in dil. sulphuric acid. It is soluble in nitric acid, and T. Dieckmann and O. Hauf added that with dil. nitric acid the amalgam forms chromous oxide and mercury. A. S. Russell and co-workers found that the order of removal of metals from mercury amalgam by an oxidizing agent is: Zn, Cd, Mn, Tl, Sn, Pb, Cu, Cr, Fe, Bi, Co, and Ni. According to J. Férée, only dil. amalgams are produced by the action of sodium amalgams on chromic chloride, or by the electrolysis of chromium salts with a mercury cathode; better results are obtained by electrolyzing a soln. containing 160 grms. of chromic chloride and 100 grms. of conc. hydrochloric acid in 740 grms. of water by means of a powerful current with a mercury cathode and a platinum anode. Using a current of 22 ampères and a mercury surface of 8·05 sq. cm. he obtained 1·5 kilo. of a solid chromium amalgam. When dried and filtered through chamois leather, the amalgam has the composition **mercury tritachromide,** Hg_3Cr. When this is subjected to a press. of 200 kgrms. per sq. cm., it loses mercury and yields **mercury monochromide,** HgCr. The first amalgam is soft, brilliant, and alters but little in air, but when heated loses mercury without melting and oxidizes rapidly; the second is brilliant and harder, but alters more readily. When distilled in vacuo below 300°, they both yield chromium which is pyrophoric at ordinary temp. M. Rabinovich and P. B. Zywotinsky observed that chromium can be dispersed in mercury above the solubility limit and so form a colloidal soln.

F. T. Sisco and M. R. Whitmore [4] obtained **aluminium-chromium alloys** with up to 5 per cent. aluminium, by direct fusion of the two elements. G. Hindrichs could not obtain alloys with more than 70 per cent. chromium by heating a mixture of the two elements in an electric furnace. The alloys were obtained by H. Moissan by reducing chromic oxide with aluminium in excess. G. Hindrichs said that the best mode of preparing the alloys is by igniting a mixture of aluminium, chromic oxide, and potassium dichromate. C. Combes obtained crystalline alloys by the action of the vapour of chromic chloride on aluminium; F. Wöhler obtained the alloys by fusing a mixture of aluminium with twice its weight of violet potassium chromic chloride, $KCrCl_4$, or of a 1 : 2 mixture of potassium and chromic chlorides; and extracting the cold mass first with water, and then with dil. alkali-lye to remove free aluminium. G. Hindrichs found that mixtures with between 5 and 55 per cent. of chromium form two liquid layers, Fig. 10, and there is evidence of the formation of **aluminium trichromide,** $AlCr_3$, whose m.p. lies above 1600°. L. Guillet obtained alloys corresponding with *aluminium chromide,* AlCr, and *aluminium tetrachromide,* $AlCr_4$, in the form of silver-grey powders of the respective sp. gr. 4·93 and 6·75 at 20°. H. Schirmeister, J. W. Richards, and E. S. Sperry made some observations on these alloys. F. Wöhler regarded his product as the monochromide, and he described it as forming tin-white, tetragonal plates, or rectangular tetragonal prisms resembling idocrase. It melts at a higher temp. than nickel, forming, when cold, a hard, brittle mass of sp. gr. 4·9. When heated in air, it acquires a steel-coloured lustre without oxidizing further; when heated in hydrogen chloride, some silicon chloride is formed from the impurities present, chromous and aluminium chlorides are also produced; hydrochloric acid attacks the alloy with the evolution of hydrogen; warm, conc. sulphuric acid develops hydrogen with the separation of sulphur; and it is not attacked by conc. nitric acid, or alkali-lye.

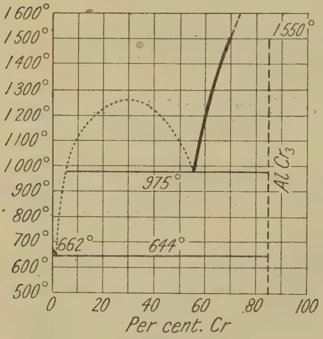

FIG. 10.—Freezing-point Curve of Al–Cr Alloys.

According to G. Hindrichs,[5] **tin-chromium alloys** are produced within a very narrow range; the f.p. of chromium is lowered by the addition of up to 10 per cent. of tin; and mixed crystals are formed up to 6 per cent. of tin—*vide* Fig. 11; beyond this, two liquid phases are formed one of which is pure tin. N. A. Puschin said that alloys are soft until about 90 at. per cent. Cr. is present, when they are hard and brittle; the e.m.f. curve of the cell Sn | *N*-KOH | SnCr_n shows no sign of either chemical combination or of solid soln. With *n* per cent. Cr, the potentials, *E* in millivolts, are:

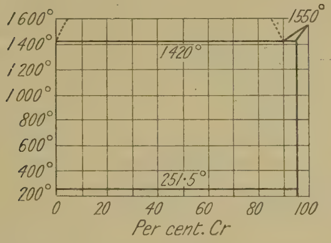

FIG. 11.—Freezing-point Curve of Sn–Cr Alloys.

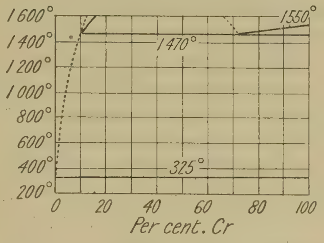

FIG. 12.—Freezing-point Curve of Pb–Cr Alloys.

n .	20	25	33	50	67	75	90	95·8	100
E .	−16	−2	−1	−1	−4	−3	−4	10	302

G. Hindrichs said that **lead-chromium alloys** can be formed by melting a mixture of the two elements above 1600°. Much lead is volatilized. The addition of 27 per cent. of lead lowers the f.p. of chromium 80°—*vide* Fig. 12; alloys with more than this proportion of lead separate into two layers one of which is lead alone, W. von Bolton obtained alloys with **tantalum and chromium.**

§ 8. The Lower Chromium Oxides

The metals of the chromium family can produce an extraordinary number of compounds;[1] they can behave as 2-, 3-, 4-, 5-, 6-, and in some cases as 8-valent elements. Hence, one element can form nearly all the types of compounds which characterize the individual elements. The lower oxides have basic properties, while the higher oxides are markedly acidic; the intermediate oxides—like those of molybdenum, tungsten, and uranium dioxides—are indifferent oxides and resemble in some respects the peroxides of lead and manganese. The lowest oxide of chromium is a strong reducing agent, while the acidic oxide acts as a strong oxidizing agent. All these elements readily form oxides with a composition intermediate between two simpler oxides, and which appear to be salt-like compounds in which the higher oxide plays the rôle of acid, and the lower oxide, base. The intermediate oxides of chromium are not analogous with those of uranium—in the first case the intermediate oxide appears as a compound of the sesqui- and tri-oxides; and in the other case, a compound of the di- and tri-oxides. The existence of the dioxide of chromium is not so unequivocally established as the dioxides of molybdenum, tungsten, and uranium; and the peroxide behaves as if it were a compound of the tri- and sesqui-oxide. Three members of the group—molybdenum, tungsten, and uranium—are closely analogous in the nature of the oxides formed, but chromium differs in many ways from the others—*e.g.* in the unstability of chromic trioxide, and the formation of no chloride higher than $CrCl_3$.

A. Moberg[2] obtained **chromium monoxide,** or **chromous oxide,** CrO, by the action of hydrogen or the vapour of alcohol on red-hot chromic oxide, and by heating chromous chloride with sodium carbonate or calcium oxide. It was also similarly obtained by L. Clouet, and E. M. Péligot. J. Férée obtained the oxide by the decomposition of chromium-amalgam in air. T. Dieckmann and O. Hauf said that the oxide is most conveniently made by the action of dil. nitric acid on chromium amalgam; the mercury passes into soln., chromous oxide remains as a black powder. Hydrogen at 1000° reduces chromous oxide to the metal. According to J. Férée, when the black powder is triturated in a mortar, it oxidizes and glows, forming chromic oxide, and likewise also when heated in air. It is insoluble in dil. nitric or sulphuric acid, and it reacts with hydrochloric acid forming a blue soln., and giving off hydrogen. Carbon dioxide at 1000° converts it into a mixture of chromic oxide and carbide. The constancy of the analytical data by J. Férée favours the assumption that it is not a mixture of chromium and chromic oxide.

If air-free aq. soln. of chromous chloride be treated with an air-free soln. of potassium hydroxide, A. Moberg found that a yellow precipitate of **chromous hydroxide,** $Cr(OH)_2$, is formed. It should be washed with air-free water in an atm. of hydrogen, or carbon dioxide, and dried over sulphuric acid. It is then dark brown. It is stable in dry air, but decomposes when heated: $2Cr(OH)_2 = Cr_2O_3 + H_2O + H_2$; it dissolves slowly in conc. acids when freshly precipitated and dried; but very little dissolves in dil. acids; and very little in boiling aqua regia. The soln. are green, and contain tervalent chromium because, said A. Moberg, chromium separates as the hydroxide dissolves. F. Allison and E. J. Murphy studied the magneto-optic properties.

The salts of this base, **chromous salts,** are obtained by reducing chromic salts—*vide infra,* chromous sulphate or chloride. The aq. soln. are red, blue, or yellow. The chromous salts readily decompose in the presence of water, forming chromic salts and hydrogen; and hydrogen is evolved when the aq. soln. are boiled or treated with platinized platinum. R. Peters said that hydrogen is liberated in the oxidation because a chromous salt soln. has a higher potential than hydrogen when in acidic soln. The reaction was studied by R. Stahn. No hydrogen dioxide was observed by W. Manchot and J. Herzog to be formed during the oxidation of chromous salts by atm. oxygen; and the amount of oxygen absorbed is simply that required for the oxidation. Hence it is inferred that the oxidation proceeds directly. According to W. Manchot and O. Wilhelms, the primary oxide formed in the oxidation of these salts is a peroxide, say CrO_2, because in the presence of an acceptor—say alcohol, or potassium arsenite—which is simultaneously oxidized, two eq. of oxygen are absorbed for each eq. of chromous oxide. J. Piccard found that in the autoxidation of neutral or acidic soln. of chromous salts, chromic acid and chromic salts are formed. Intermediate products, stable for a measurable period, are formed—*vide infra*, chromous chloride. There is first, the easily decomposed hypothetical oxide, represented by $(HO)_2Cr.O.O.Cr(OH)_2$, which acts on potassium iodide in almost neutral soln. It decomposes into the labile oxide $CrO(OH)_2$ by a unimolecular reaction. This oxide in the absence of potassium iodide forms chromic acid, but in the presence of potassium iodide, it is reduced more rapidly than it can form chromic acid. The next oxide,  $(HO)_2Cr{<}\begin{matrix}O\\ \vert\\ O\end{matrix}$, is reduced by potassium iodide in weakly acidic soln. within two minutes. W. Traube and W. Lange found that with chromous hydroxide, oxalic, hydrocyanic, and thiocyanic acids are converted into glycollic acid, methylamine, and hydrogen sulphide, respectively. Azides and azoimide instantaneously yield nitrogen and ammonia. Chloroacetic acid is converted into acetic acid, whilst benzaldehyde yields benzyl alcohol—*vide infra*, chromous chloride.

R. Bunsen[3] reported an oxide $2CrO.Cr_2O_3$, or $3CrO.Cr_2O_3$, to be formed in the electrolysis of soln. of chromic salts—*vide supra*, the electrolytic preparation of chromium. The black, amorphous powder glows when heated in air forming green chromic oxide; it is insoluble in acids. A. Geuther could not prepare an oxide of this composition; and J. Férée obtained a black powder with similar properties, but with the composition $Cr_2O_3.H_2O$, in his study of the electrolysis of soln. of chromic chloride.

According to E. M. Péligot,[4] when an air-free aq. soln. of chromous chloride is treated with air-free alkali-lye in an inert atm., the brown precipitate which is formed gradually in the cold, rapidly when boiled, decomposes, hydrogen is evolved, and a reddish-brown hydrate of **chromosic oxide**, or **chromium tritatetraoxide**, Cr_3O_4, or $CrO.Cr_2O_3$, is formed. This can be washed with boiling water, and dried in vacuo. According to A. Moberg, and G. Baugé, it is a *trihydrate*, whereas E. M. Péligot said that it is a *monohydrate*. G. Baugé could not make the monohydrate, but he obtained the trihydrate, $Cr_3O_4.3H_2O$, by treating chromous carbonate with alkali carbonate in boiling water while protected from air. The brown powder loses water when heated, and it suffers autoxidation: $2Cr_3O_4+2H_2O=3Cr_2O_3+H_2+H_2O$. According to G. Baugé, when dried in vacuo at 100°, the yellowish-brown powder has a sp. gr. 3·49. It is converted into chromic oxide by the action at 250° of water-vapour, hydrogen chloride, or an inert gas, hydrogen being evolved; it is also decomposed by chlorine at a dull red-heat, giving chromyl chloride, water, and hydrogen chloride. Although stable in dry air at the ordinary temp., it is rapidly oxidized to chromic oxide in presence of water or when heated; by hydrogen sulphide, it is converted at a somewhat elevated temp. into a crystalline sulphide, whilst it rapidly reduces dil. sulphuric acid at 40°, hydrogen sulphide being evolved if a large quantity of the oxide is employed. When the latter is dissolved in conc. hydrochloric acid, a mixture of chromous and chromic chlorides is formed.

§ 9. Chromic Oxide

Chromium oxidizes when heated in air to form **chromium hemitrioxide, chromium sesquioxide,** or **chromic oxide,** Cr_2O_3; chromic oxide is also produced by calcining the hydroxide—*vide supra*, the extraction of chromium. The analysis of J. J. Berzelius [1] corresponds with this formula; and it is usually supposed to be constituted $O{=}Cr{-}O{-}Cr{=}O$; although A. T. Cameron assumed the formula to be $Cr{\equiv}O_3{\equiv}Cr$. L. N. Vauquelin, H. Moser, J. Persoz, and J. B. Trommsdorff obtained this oxide by heating mercuric chromate; it has a fine green colour if calcined out of contact with air, but it has a brown colour when heated while exposed to air. A. Maus obtained it by heating ammonium chromate; A. A. Hayes, ammonium dichromate: $(NH_4)_2Cr_2O_7{=}4H_2O{+}N_2{+}Cr_2O_3$; J. L. Lassaigne, and H. Moser, a mixture of potassium chromate and sulphur, and extracting the soluble products with water; G. C. Wittstein, H. C. Roth, and E. Dieterich, a mixture of potassium dichromate and sulphur; F. Wöhler, a mixture of potassium dichromate, ammonium chloride, and sodium carbonate; R. T. M. y Luna, G. B. Frankforter and co-workers, a mixture of potassium dichromate and ammonium chloride; and A. L. D. d'Arian, alkali chromate and ammonium sulphate. According to V. H. Roehrich and E. V. Manuel, the reaction between ammonium chloride and potassium dichromate, usually symbolized by R. T. M. y Luna's equation $2NH_4Cl{+}K_2Cr_2O_7{=}Cr_2O_3{+}2KCl{+}4H_2O{+}N_2$, varies with the temp. at which the mixture is heated and the relative proportions of the constituents of the mixture. The first visible sign of change occurs at 210° when the mixture becomes yellowish-brown owing to the formation of a chromium dioxide; at 260°, a slate-coloured residue is obtained which when lixiviated with water gives greenish-black crystals of a hydrated chromic oxide. At 370°, with an excess of ammonium chloride, chromium chloride and ammonia are formed; with the potassium dichromate in excess a black residue mixed with unchanged dichromate is formed. Under different conditions chlorine, nitric oxide, nitrogen peroxide and chromium nitride may be formed as by-products. C. H. Binder obtained chromic oxide by heating a mixture of potassium dichromate and starch; C. H. Humphries, from a mixture of chromium trioxide and barium hydroxide. R. Böttger inflamed a mixture of picric acid, potassium dichromate, and ammonium chloride; H. Schöffer inflamed a mixture of sodium dichromate and glycerol; W. Carpmael heated an aq. soln. of an alkali chromate and an organic reducing agent—sugar, sawdust, etc.—above 110°, under press.; and E. A. G. Street obtained it as a product in the electrolysis of a soln. of an alkali chromate with a mercury cathode. F. Wöhler, and J. F. Persoz found that the crystalline oxide is formed when chromyl chloride is decomposed by heat; W. P. Evans, when chromyl fluoride is heated; E. Frémy, when heated potassium chromate is decomposed by chlorine; W. Müller, when potassium chromate at a red-heat is decomposed by hydrogen chloride; V. Kletzinsky, when potassium chlorochromate is melted; J. C. Gentele, when potassium dichromate is decomposed at a high temp.; R. Otto, when potassium dichromate is decomposed by hydrogen at an elevated temp.; A. Ditte, and H. Schiff, when potassium dichromate is decomposed by fusion with sodium chloride; and M. Prud'homme, when potassium dichromate is heated with tin. Crystals of chromic oxide are often produced as a kind of sublimate when mixtures containing chromic oxide are heated in closed vessels in pottery ovens. E. Wydler, and G. F. C. Frick also described the preparation of the oxide; and W. P. Blake and W. H. Miller observed its formation as a furnace product. C. Ullgren obtained crystals of the oxide by decomposing potassium dichromate mixed with oil, or ammonium chloride and then raising the temp. to a white-heat. V. Kohlschutter and J. L. Tüscher obtained highly dispersed or an **aerosol of chromic oxide** by vaporizing the oxide into a chamber where it is suddenly chilled.

The physical properties of chromic oxide.—The **colour** of amorphous chromic oxide is bright green if it has been calcined in a reducing atm., and it may acquire a brown tinge in an oxidizing atm. The tint of commercial oxides varies from brownish-green, to greyish-green, to olive-green to bright grass-green. This may be due to partial crystallization; to the grain-size of the powder; and to the presence of traces of impurity as a result of which the colour of a chromate may be superposed on that of the chrome-green. The amorphous chromic oxide obtained from ammonium dichromate is a voluminous, tea-green powder. A very thin sublimate of chromic oxide is red, and this probably explains the colour of the chrome-tin pink, **1**. 46, 33; and of the ruby, **5**. 33, 10. R. Klemm found a relationship between the proportion of chromium in spinel, corundum, spodumene, beryl, chrysoberyl, topaz, and zircon and the depth of colour. In all but zircon, chromium replaces aluminium, and in zircon, it may replace silicon or zirconium. Small quantities of vanadium may take the place of chromium. Black chromic oxide, insoluble in acids, was obtained by L. Godefroy by heating the hydrate, $Cr_2O_3.3H_2O$; and by E. A. Werner, by heating the succinate. According to O. Hauser, the play of colours of the variety of chrysoberyl called *alexandrite* is produced by a small trace of chromic oxide. I have evidence that the colour of chrome-tin pink or crimson—produced by a trace of chromic oxide on stannic oxide as mordant—probably represents the colour of the highly dispersed chromic oxide. The colour can be produced by depositing the vapour of chromic oxide on stannic oxide or on alumina. According to A. Duboin and others, the colour of the ruby is due to the presence of chromic oxide—**5**. 33, 10. The red colour of the so-called chrome-tin crimson is thus equivalent to the crimson and purple colour of the purple of cassius where colloidal gold is dispersed on the same mordant; and also equivalent to the copper red—*rouge flambé*—where presumably colloidal copper is deposited on the same mordant. The chrome-tin crimson has been discussed by H. A. Seger, F. Rhead, A. S. Watts, R. C. Purdy and co-workers, W. A. Hull, W. A. Lethbridge, L. Petrik, and T. Leykauf—*vide infra*, stannic chromate. C. W. Stillwell said that the red colour of rubies is not due to colloidal chromic oxide; that it is not due to higher or lower oxides of chromium; nor to variations in the proportion of chromic oxide present. He assumed that the red colour is due to a second modification of chromic oxide, of the same crystal structure as the green modification and alpha alumina, whose axial ratio is nearer to that of alpha alumina than is the axial ratio of the green modification. Therefore, the red modification tends to form when chromic oxide is added to alpha alumina and does form under ordinary conditions up to a certain point, beyond which the effect of the alumina is not strong enough to stabilize it. The occurrence of the red or green modification depends on the value of the axial ratio of the mixed crystal. There is a discontinuity in the change of the axial ratio with change in chromic oxide content when one modification changes to the other. There is also a marked difference in the axial ratio of a mixed crystal containing the red form of chromic oxide and a crystal containing the same amount of chromic oxide in the green form. This change in axial ratio may be affected in two different ways—*e.g.* by varying the proportion of chromic oxide, or by varying the nature of the atm. in which the mixture is fused.

L. Blanc showed that the blue, amorphous oxide, which he designates α–Cr_2O_3, is rapidly transformed into the green, crystalline oxide—β–Cr_2O_3—at 700°. L. Blanc and G. Chaudron added that the exothermal passage of the blue, precipitated α–Cr_2O_3 to olive-green β–Cr_2O_3, occurs at 500° in air and at 750° in vacuo. The blue oxide absorbs oxygen rapidly at 200°, forming CrO_2 and Cr_5O_9. Both these form β–Cr_2O_3 and a black oxide at 440°, and if kept several hours at 350°, a larger proportion of the black oxide is formed. It is decomposed at 450°–500° yielding β–Cr_2O_3. Guignet's green, or finely divided β–Cr_2O_3, gives the black oxide on oxidation. Hence there are two oxides of the formula Cr_5O_9 with a transition temp. If the amorphous chromic oxide be heated in a gas-blowpipe, and cooled, E. Frémy, and M. Z. Jovitschitsch said that the product is crystalline ; and H. Moissan, also, by heating the oxide in the electric arc-furnace. T. Sidot crystallized the oxide by heating it in a current of oxygen ; J. J. Ebelmen, by strongly heating it with calcium carbonate and boric oxide ; and P. Ebell, by dissolving the oxide in molten glass at a high temp.—the oxide crystallizes out as the glass is slowly cooled.

Crystalline chromic oxide forms lustrous black **crystals,** or a green powder. According to G. Strüver, the trigonal crystals have the axial ratio $a : c = 1 : 1{\cdot}3770$, and $\alpha = 85° \ 22'$. The crystals were also examined by G. Rose, W. H. Miller, W. P. Blake, and J. J. Ebelmen. The **cleavage** on the (100)-face is well-defined. According to G. Rose, the crystals are isomorphous with the corresponding aluminium and ferric oxides. W. P. Davey found that the **X-radiograms** correspond with a diamond lattice except that the cube is stretched along its body-diagonal. The side of the unit triangle is 4·745 A. ; and the high axial ratio, 2·764, is explained by assuming a hexahedral molecule consisting of an equilateral triangle of oxygen with a metal atom immediately above and below the centre of the triangle ; there are three molecules per unit prism—**5.** 33, 10. W. H. Zachariasen made observations on this subject and obtained for the axial ratio $a : c = 1 : 1{\cdot}374$; and for the parameter $r = 5{\cdot}35$ A. L. Passerini gave for the hexagonal cell $a = 4{\cdot}950$ A., $c = 6{\cdot}806$ A. ; with $a : c = 1 : 1{\cdot}374$, $v = 143{\cdot}4 \times 10^{-24}$ c.c., and density 5·283 ; and for the rhombohedral cell, $a = 5{\cdot}38$ A., and $\alpha = 54° \ 50'$; whilst P. E. Wretblad gave for the hexagonal cell, $a = 4{\cdot}949$ A., $c = 13{\cdot}57$ A., $a : c = 1 : 2{\cdot}7412$, and $\alpha = 55° \ 11'$. L. Passerini, and V. M. Goldschmidt and co-workers studied the solid soln. with alumina, and with ferric oxide (*q.v.*). W. Müller said that the oxide prepared by reducing potassium chromate with dry—not moist—hydrogen chloride is quite different from the ordinary oxide, being greyish-green, composed of tube-like plates of the hardness of graphite.

F. Wöhler found the **specific gravity** of the crystalline oxide to be 5·21 ; L. Playfair and J. P. Joule gave 4·909 ; H. Schröder, 5·010 ; H. Schiff, 6·2 ; W. A. Roth and G. Becker, 5·20 to 5·21 at 21° ; and E. Wedekind and C. Horst, 5·21 ; L. Blanc found that the oxide calcined from 500° to 800° has a sp. gr. 5·033 ; at 820°, 5·110 ; at 1080°, 5·130 ; and when fused, 6·145. H. P. Walmsley gave 5·238 for the sp. gr. of the dispersed oxide ; and W. H. Zachariasen, 5·25, calculated from the X-radiogram data. W. Biltz and co-workers found the mol. vol. of chromic oxide in the spinels to be 28·9. F. Wöhler found that crystalline chromic oxide has a **hardness** great enough for it to scratch quartz, topaz, and hyacinth ; and G. Rose, and W. P. Blake found that it is as hard as corundum. O. Ruff and A. Riebeth discussed the **plasticity** of mixtures of the oxide with water, etc.

H. V. Regnault gave 0·1796 for the **specific heat ;** F. E. Neumann, 0·196 ; and H. Kopp, 0·177 for the crystalline oxide. A. S. Russell found 0·0711 for the sp. ht. between −191° and −80·3° ; 0·1474, between −76·5° and 0° ; and 0·1805, between 2·6° and 49·3° and for the **molecular heat,** 10·81 at −136° ; 22·40 at −38° ; and 27·4 at 26°. J. Maydel discussed some relations of the sp. ht. J. J. Berzelius, H. Moissan, and J. Weise observed that the precipitated hydrated oxide exhibits **calorescence** when heated—*vide* alumina, **5.** 33, 10—and at the same time becomes denser, and less soluble in acids. W. G. Mixter said that the glowing occurs between 500° and 610°. J. J. Berzelius, L. Wöhler, and K. Endell and R. Rieke gave 500° ; H. le Chatelier, 900° ; L. Blanc, 550° to 600° ; G. Rothaug, 420° to 680°, according as the precipitate is pulverulent or granular—and he added that particles may be projected from the crucible at this temp. H. Moissan, H. le Chatelier, and W. G. Mixter regarded the change as evidence of the passage from one allotropic form to another. L. Wöhler found that the calorescence is independent of the surrounding atm. and the humidity. The temp. of calorescence is lowered by increasing the quanity of material. With 8 grms. of chromic oxide, the temp. in dry hydrogen is 530°–550°, although in air or oxygen it begins at 425° on account of the exothermal decomposition of the chromium dioxide which is formed. The calorescence is hindered by precipitation with ammonia from soln. containing sulphate, and favoured by a low conc. of the chromic salt soln. L. Wöhler and M. Rabinowitsch found that the thermal value of the calorescence is 8 to 11 cals. per gram according as the oxide is precipitated from conc. or dil. soln. The change to the sintered oxide by calorescence is never complete. The oxide formed with the greatest heat development is the best absorbent for *m*-nitrobenzoic acid. M. Siewert showed that the glowing temp. depends on the rate of heating; and L. Wöhler, that the glowing is increased by conditions which favour hydrosol formation in the preparation of the hydrated oxide; and it is greater in proportion to the adsorption capacity of the precipitate. This agrees with the hypothesis that the phenomenon is connected with the surface area of the particles, and is due to a sudden decrease in the large surface of the oxide prepared by precipitation. J. Böhm found that the X-radiograms of chromic oxide before and after the calorescence showed that the glowing is attended by the passage of the oxide from the amorphous to the crystalline state. E. D. Clark found that chromic oxide melts in the oxy-hydrogen blowpipe flame giving off white fumes, but without reduction; E. Tiede and E. Birnbräuer studied the action of high temp. on the oxide. H. Moissan melted it in the electric furnace. C. W. Kanolt gave 1990° for the **melting point** of chromic oxide. L. Elsner observed that chromic oxide volatilizes in the porcelain ovens—presumably at 1500°–1600°. I have noticed evidence of its volatilization in pottery ovens at as low a temp. as 1050°; and C. Zengelis obtained evidence of its volatilization at ordinary temp. W. R. Mott gave 3000° as an approximation to the **boiling point.** F. Born calculated the **dissociation pressure** of chromic oxide at 2000° to be 3 mm., and at 3000°, over 760 mm. H. von Wartenberg and S. Aoyama gave for the partial press. of the oxygen at 600° and 1130° respectively $p_{O_2}=6{\cdot}73\times10^{-37}$ and $3{\cdot}07\times10^{-13}$. W. G. Mixter gave for the **heat of formation** of crystalline chromic oxide $(2Cr,1\frac{1}{2}O_2)$ $=267{\cdot}8$ Cals.; for the stable amorphous oxide, 266 Cals.; and for the unstable oxide, 243 Cals. H. von Wartenberg gave 265·8 Cals.; and W. A. Roth and G. Becker, 288·0 Cals. H. von Wartenberg and S. Aoyama calculated 279 Cals. The subject was discussed by H. Collins.

E. L. Nichols and B. W. Snow measured the **reflecting power** of chromic oxide; and M. Luckiesh found that for light of wave-length λ in μ:

λ . .	0·44	0·48	0·54	0·56	0·60	0·64	0·70
Light green .	10	14	23	20	11	9	6 per cent.
Medium green	7	10	17	13	7	6	5 per cent.

W. W. Coblentz found for the ultra-red reflecting power:

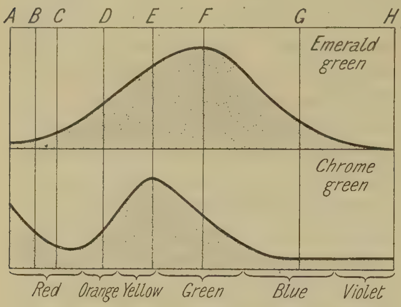
λ	0·60	0·95	4·4	8·8	24·0μ
Reflecting power .	27	45	33	5	8 per cent.

and for the **ultra-red emission spectrum,** he obtained for the diffuse reflecting power:

λ	0·54μ	0·60μ	0·95μ	4·4μ	8·8μ	24·0μ
Emission . .	24·1	27·0	46·4	32·9	5·0	8·2

The results are illustrated by Fig. 15, where the green oxide furnishes a fairly smooth spectrum with a possible maximum at 5μ, and a depression at 3·2μ. H. Schmidt-Reps studied this subject. G. Liebmann found the emissive power for visible red-light between 1208° K. and 2000° K. decreases with decreasing grain-size; it is independent of temp.; and increases rapidly with decreasing wave-length—*e.g.* for green light.

A. Dufour examined the **flame spectrum**; K. Skaupy, the heat radiation from the incandescent oxide; and W. N. Hartley, the spectrum of the oxide in the oxy-hydrogen flame. G. H. Hurst showed that with emerald-green pigment nearly all the green rays are reflected and only a small proportion of other rays, Fig. 13, while with chrome-green pigment, the green rays are reflected nearly in their full intensity, Fig. 14, but there is also reflected a portion of the red, blue, and violet rays. Hence the deeper tone of chrome-green in comparison with emerald-green. T. Dreisch studied the ultra-red absorption spectrum of glass coloured with chrome oxide. R. Robl observed but a faint luminescence in ultra-violet light. H. S. Patterson and R. Whytlaw-Gray studied the photophoresis of chromic oxide aerosols; and R. Whytlaw-Gray and co-workers, and E. Thomson found that particles exhibiting the Brownian movement form chains in an electrostatic field. C. Doelter observed no coagulation in radium rays; W. P. Jorrissen and H. W. Woudstra also studied the phenomenon. J. Vrede found the oxide to be of no use as a **radio-detector**.



FIGS. 13 and 14.—Reflection Spectra of Emerald-green and Chrome-green.

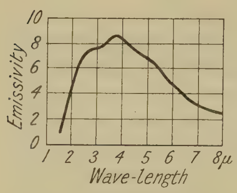


FIG. 15. — Ultra-red Emission Spectrum of Chromic Oxide.

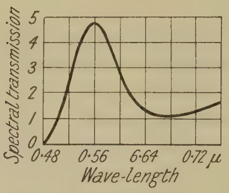

FIG. 16.—Spectral Transmission Factor of Chrome Green.

E. Friederich calculated $2\cdot9\times10^9$ for the **electrical resistance** of a metre of wire 1 sq. mm. section. According to M. Faraday, and L. F. Nilson and O. Pettersson, chromic oxide is magnetic. S. Meyer found the **magnetic susceptibility** to be $X=24\times10^{-5}$ mass units at 17°; and E. Moles and F. Gonzalez, $26\cdot2\times10^{-6}$. Comparative measurements were made by P. Hausknecht. E. Wedekind and co-workers gave $25\cdot97\times10^{-1}$ mass units at 16°; L. Blanc and G. Chaudron found an abrupt increase at 880° followed by a fall at 900°. G. Chaudron and H. Forestier observed that the coeff. of susceptibility of calcined chromic oxide is greater than that of the uncalcined oxide. S. Veil studied this subject. K. Honda and T. Sone gave :

	−186°	−64°	−3°	17·6°	64°	117°	644°	1335°
$\chi\times10^6$ . .	20·1	22·2	24·6	25·5	26·0	25·6	17·7	12·6

The chemical properties of chromic oxide.—E. D. Clarke said that chromic oxide is not decomposed by the oxyhydrogen blowpipe flame; and J. J. Berzelius found that it is not decomposed by **hydrogen** at a red-heat. For the electroxidation of chromic oxide, *vide* chromic acid, etc. According to R. Saxon traces of chromic acid are formed by the anodic oxidation of chromic oxide in pure water; the addition of manganese dioxide to the chromic oxide increases slightly the yield of chromic acid. Much more rapid oxidation ensues in the presence of calcium or potassium hydroxide or both. In soln. of alkali chlorides containing a little chrome-alum, chromic oxide is rapidly oxidized at the anode to chromic acid. K. Fischbeck and E. Einecke found that powdered chromic oxide is not perceptibly reduced when used as anode in the electrolysis of 2 per cent. sulphuric acid. The adsorption of hydrogen by the $ZnO–Cr_2O_3$ catalyst was studied by W. E. Garner and F. E. T. Kingman; whilst O. Schmidt, and A. F. Benton studied the adsorption of hydrogen by chromic oxide; and also the adsorption of **oxygen**. H. N. Warren, and H. von Wartenberg found that chromic oxide is reduced to the metal by hydrogen at 5 atm. press., and at 2500° ; and E. Newbery and J. N. Pring, by hydrogen at 2000° and 150 atm. press. H. von Wartenberg and S. Aoyama found that whereas iron oxides are reduced at 1100° when pH_2O/pH_2 is about 1, this ratio must be about 0·001 for the reduction of chromic oxide. Hence, since water is produced in the reduction, an enormous excess of hydrogen would be needed to reduce any quantity of chromic oxide, and there is no possibility of such a process being used instead of the alumino-thermic process for preparing carbon-free chromium. The heat of reaction calculated from these results agrees with the value for the heat of formation of chromic oxide from chromium, and it is inferred that chromous oxide is not an intermediate stage at these temp. (600–1400°)—*vide supra*, chromium. H. Moissan found that when chromic oxide is heated in oxygen to about 440°, some chromium dioxide is formed which decomposes into ordinary chromic oxide at a higher temp. According to L. and P. Wöhler, no oxidation occurs when chromic oxide is heated to 1220°, and they suggest that the formation of higher oxides must be an endothermal process taking place at higher temp. If chromic oxide is heated along with potassium sulphate in an atm. of oxygen at about 1000°, an equilibrium press. is established, which increases when the temp. is lowered, and decreases when the temp. is raised. This is therefore a case of exothermic dissociation, and the equilibrium is probably : $2K_2SO_4+Cr_2O_3+3O\rightleftharpoons 2K_2SO_4+2CrO_3$. The value of the equilibrium press. at any temp. varies with the quantity of oxygen already absorbed, probably because at 1000° potassium sulphate is fused and keeps the complex compound in soln. G. Rothaug found that the formation of chromic chromate, $5Cr_2O_3+9O\rightleftharpoons 2Cr_2(CrO_4)_3$, is a maximum at 300° and can be observed at 100°. The rate of the oxidation falls rapidly to 400°, and after that proceeds slowly. R. Schwarz added that the ignition of chromic oxide is best carried out in a platinum crucible since the reducing gases passing through the platinum hinder the formation of the chromic chromate, Cr_5O_{12}. Chromic oxide is insoluble in **water**—for the hydrates, *vide infra*. The oxide which has not been heated above the temp. at which it caloresces is more chemically active than otherwise. Thus, M. Traube and others showed that the chromic oxide obtained at a low temp. dissolves slowly, if at all, in **acids,** but not so if the oxide has been heated to a high temp. H. le Chatelier gave 900° as the temp. at which chromic oxide becomes insoluble in acids. A. Mailfert observed that **ozone** oxidizes chromic oxide. H. Moissan found that at 400°, moist **chlorine** reacts with dry chromic oxide forming chromyl chloride ; and R. Weber found that if the oxide has been dehydrated below the temp. of calorescence, it is easily attacked by dry chlorine to form chromyl chloride ; the calcined oxide is attacked by chlorine at a red-heat. If the chromic oxide is mixed with carbon, and heated in a current of dry chlorine, chromic chloride is formed. H. Moissan observed that the calcined oxide is not attacked by chlorine or by **bromine ;** and J. Weise added that the calcined oxide can be dissolved by **hydrofluoric acid** if a trace of chromic anhydride is present. K. Fredenhagen and G. Cadenbach found chromic oxide to be indifferent towards hydrofluoric acid. The attack by chlorine was studied by R. Wasmuth. O. Ruff and H. Krug found that chromic oxide is attacked with incandescence by **chlorine trifluoride**. G. Gore observed that liquid **hydrogen chloride** does not dissolve any chromic acid during 6 days' digestion.

J. L. Lassaigne, and K. Brückner found that chromic oxide is not attacked by **sulphur** vapour at a white-heat. H. Moissan observed that the oxide which has not been heated to a high temp. forms chromic sulphide when heated to 440° in a current of **hydrogen sulphide ;** but the calcined oxide is not attacked by this gas. C. Matignon and F. Bourion observed that when the oxide is heated in a current of **sulphur monochloride** and chlorine, chromic chloride is formed ; and R. D. Hall obtained a similar product with sulphur monochloride alone. F. Bourion found that the reaction begins at about 400°. G. Darzens and F. Bourion found that **thionyl chloride** at 400° also converts the chromic oxide into the chloride. L. and

P. Wöhler observed that **sulphur dioxide** does not reduce the oxide at a red-heat; and L. and P. Wöhler and W. Plüddemann studied its catalytic action in the oxidation of sulphur dioxide. H. P. Cady and R. Taft found the oxide to be insoluble in liquid sulphur dioxide, while chromic oxide which has been calcined at a high temp. does not dissolve in **sulphuric acid.** J. Weise said that if a trace of chromic acid be present, chromic oxide passes into soln. T. Sabalitschka and F. Bull said that fusion with **sodium pyrosulphate** is the best way to bring ignited chromic oxide into soln.

H. C. Wolterick found that when a mixture of **nitrogen** and hydrogen is passed over chromic oxide at 550°, a little ammonia is formed, and, according to H. N. Warren, some nitride as well; O. Schmidt studied the adsorption of nitrogen by chromic oxide, and also of **ammonia**. J. E. Ashby found that heated chromic oxide favours the combustion of ammonia in air. D. Maneghini studied it as a catalyst in the oxidation of ammonia. F. Ephraim observed that chromic oxide is attacked by **sodium amide**. M. Z. Jovitschitsch found that chromic oxide dissolves when digested for 10 hrs. with fuming or conc. **nitric acid;** the calcined oxide does not dissolve in nitric acid. R. Weber found that if strongly heated with **phosphorus pentachloride** chromic oxide furnishes the chloride. C. Lefèvre studied the action of **alkali arsenates** on chromic oxide.

J. J. Berzelius found that chromic oxide at a white-heat is decomposed by **carbon;** and H. C. Greenwood added that the reaction begins at about 1180°—*vide supra*, chromium. R. E. Slade and G. I. Higson said that the equilibrium press. of the oxide in contact with carbon at 1292° is 6·2 mm., and at 1339°, 9·2 mm. O. Heusler found that the carbon monoxide press. between 1480° and 1801° increases from 18 to 760 mm. The energy consumption for the liberation of a mol of carbon-monoxide is 52·8 Cals. The equilibrium between 886° and 1096° is represented by $\log K=11{\cdot}375-11550p^{-1}$. J. F. Gmelin, F. Göbel, and I. L. Bell observed that chromic oxide is not reduced by **carbon monoxide,** and G. Charpy said that this gas does not act on chromic oxide at 1000°. K. Chakravarty and J. G. Ghosh studied its catalytic action on the reaction between carbon monoxide and hydrogen; and W. E. Garner and F. E. T. Kingman, the adsorption of the gas by the $ZnO-Cr_2O_3$ catalyst. O. Schmidt, and A. F. Benton studied the adsorption of carbon monoxide and of **carbon dioxide** by chromic oxide; and O. Schmidt of **ethane** and **ethylene.** E. Demarçay, and H. Quantin found that **carbon tetrachloride** reacts with chromic oxide at a red-heat forming chromic chloride, phosgene, and carbon dioxide. P. Camboulives said that the reaction occurs at 580°. H. Rose observed that **carbon disulphide** at a white-heat forms chromic sulphide (*q.v.*). A. Kutzelnigg observed no oxidizing action on a soln. of **potassium ferrocyanide**. J. Milbauer found that molten **potassium thiocyanate** forms the sulpho-salt $K_2Cr_2S_4$. J. E. Ashby, J. R. Huffmann and B. F. Dodge, W. E. Garner and F. E. T. Kingman, W. A. Lazier, and H. H. Storch observed the catalytic action of chromic oxide in the oxidation of **alcohol, ether,** and **volatile oils**. W. Eidmann found chromic oxide to be insoluble in **acetone;** and H. Bodenbender found it to be soluble in a soln. of **calcium sucrate**—a litre of a soln. containing 418·6 grms. of sugar and 34·3 grms. of calcium oxide dissolves 1·07 grms. Cr_2O_3; a litre of a soln. containing 296·5 grms. of sugar and 24·2 grms. of calcium oxide dissolves 0·56 grm. of Cr_2O_3; and a litre of a soln. with 174·4 grms. of sugar and 14·1 grms. of calcium oxide dissolves 0·20 grm. of Cr_2O_3. A. Löwenthal studied its catalytic action in the oxidation of hydrocarbons and alcohol; L. J. Simon, the oxidation of organic substances; M. R. Fenske and P. K. Frolich, the formation of alcohol from carbon monoxide and hydrogen; J. R. Hoffman and B. F. Dodge, the formation and decomposition of methanol; and A. E. Tschitschibabin, the reaction between ammonia and acetylene. The use of chromic oxide as a mordant in the dyeing of **wool, cotton,** and **silk** was discussed by L. Liechti and J. J. Hummel, and W. D. Bancroft. The last-named said that from dichromate soln. wool first adsorbs chromic acid and this is reduced to chromic oxide, which is the true mordant; within limits, increasing the acid conc. increases the chromic acid taken up ; chromic acid oxidizes organic compounds more readily in presence than in absence of wool ; when wool is mordanted with chrome alum, a basic sulphate changing later to chromic oxide is first formed ; silk adsorbs chromic oxide less strongly than wool does ; cotton takes up scarcely any chromic oxide from chrome alum, but adsorbs it from an alkali soln. ; there is no evidence of the formation of any definite compound when wool is mordanted with chromic oxide. A. W. Davison discussed the adsorption of chromic oxide by **leather ;** H. Rheinboldt and E. Wedekind, the adsorption of organic dyes by chromic oxide.

A. Fodor and A. Reifenberg found that **silicic acid** peptizes ignited chromic oxide forming a colloidal soln. W. Guertler showed that the oxide is slightly soluble in molten **boric oxide** producing a green coloration. S. Kondo, and C. E. Ramsden examined the solubility of chromic oxide in pottery **glazes.** The reducing action of **boron** on heated chromic oxide was observed by A. Binet du Jassonneix ; of **silicon,** by B. Neumann, and P. Askenasy and C. Ponnaz. L. Kahlenberg and W. J. Trautmann observed that when mixed with silicon, there is no reaction if heated by a bunsen burner, a slight reaction at a cherry-red heat, and a good reaction in the electric arc. E. N. Bunting studied the binary system of chromic oxide and **silica.** H. von Wartenberg and H. Werth found that when heated with **zirconia,** no compound is formed, but a eutectic appears at about 2200° with about 50 per cent. of chromic oxide.

The reducing action of **potassium** and **sodium** was observed by J. J. Berzelius ; of **calcium,** by A. Burger ; of **magnesium,** by J. Parkinson, and L. Gattermann—*vide supra*, chromium ; of **aluminium**—*vide supra*, chromium ; and the colouring effect on glass by K. Fuwa. For the action of **metal oxides,** *vide infra*, the chromites. H. D. Rankin got chromite into soln. by heating it to redness and afterwards treating it with alkali-lye under press. H. Schiff found that chromic oxide is attacked with difficulty by fused **potassium nitrate.** According to J. von Liebig and F. Wöhler, E. Bohlig, and F. H. Storer, chromic oxide is attacked and oxidized by fused **potassium chlorate, hydrosulphate,** and **permanganate ;** by any suitable base in the presence of air or oxygen ; and by **lead dioxide,** or **manganese dioxide** in the presence of sulphuric acid. For the action of permanganates, *vide* the permanganates. T. Sabalitschka and F. Bull said that chromic oxide is incompletely soluble in fused **potassium pyrosulphate ;** to open the oxide up for analysis, it is preferable to fuse the substance with a mixture of 2 parts of sodium carbonate and 1 part of potassium nitrate for 10 min. The mass is dissolved in water and the insoluble residue fused with pyrosulphate. F. Hans found that chromic salts are oxidized by silver salts in accord with $Cr_2O_3+3Ag_2O=2CrO_3+6Ag$. J. Hargreaves and T. Robinson found that when mixed with **alkali chloride,** and heated in air or oxygen, chlorine is evolved, and in moist air, hydrogen chloride.

§ 10. Hydrated Chromium Oxides. Chromium Hydroxide

Some of the *chrome ochres*—**6**. 40, 49—contain hydrated chromic oxide. According to W. Ipatieff and A. Kisseleff,[1] if $2N$-H_2CrO_4 at 240°–300° be exposed to hydrogen at 150° to 180° atm. press., a heavy, greyish-violet, slightly crystalline precipitate of **chromic oxyhydroxide,** $Cr_2O_3.H_2O$, or $CrO(OH)$, is formed ; if in 25 c.c. of soln., 4 c.c. of $\frac{1}{10}N$-H_2SO_4 be present, in a gold tube, a similar violet-grey precipitate is formed at 300° to 325° ; and in a quartz tube, the crystals are green, and cubic. If more sulphuric acid is present, at 300°, and 180 to 200 atm. press., two kinds of crystals are formed. According to W. Ipatieff and B. Mouromtseff, a nitric acid soln. of chromic nitrate when exposed to hydrogen at 320°–360°, under a press. of 200–370 atm., for 12–24 hrs., gives monohydrated chromium oxide closely resembling chrome ochre. If air is used in place of hydrogen, smaller crystals are obtained and the separation is not quantitative, a portion of the oxide being converted into chromic acid. Small amounts of dark red crystals are also occasionally obtained. According to J. B. Trommsdorff, if soln. of chromic salts are treated with alkali hydroxides, or aq. ammonia, it is best to work with boiling soln. It is difficult to wash the precipitated hydrated chromic oxide free from adsorbed salts. The product has been called **chromic hydroxide,** $Cr(OH)_3$, but it is generally supposed to be a colloidal hydrated oxide of less definite composition. O. Ruff and B. Hirsch studied the fractional precipitation of chromic hydroxide in the presence of salts of other metals. S. Hakomori said that the reason ammonia does not precipitate hydrated chromic oxide in the presence of tartaric acid is because a complex salt is formed; and not in the presence of glycerol, because of colloidal phenomena induced by the high viscosity of the soln. The complex tartrate-ions were studied by K. Jellinek and H. Gordon.

J. J. Berzelius obtained a similar product by boiling a mixed soln. of potassium chromate and pentasulphide; G. F. C. Frick, by boiling a soln. of potassium chromate with sulphur; G. Lösekann, by the action of hydrogen sulphide on an alkaline soln. of a chromite oxide; H. Baubigny, by the action of hydrogen sulphide on a soln. of potassium dichromate; J. Casthelaz and M. Leune, by the action of zinc hydroxide, carbonate, or sulphide, or of aluminium hydroxide, or of zinc in a feebly acid soln. of green chromic chloride; and K. Seubert and A. Schmidt, by the slow action of magnesium on a warm soln. of a chromic salt. P. A. Thiessen and B. Kandelaky prepared the hydroxide free from adsorbed electrolytes by the hydrolysis of chromic ethylate: $2Cr(OC_2H_5)_3+6H_2O=Cr_2O_3.3H_2O+6C_2H_5OH$. A. Simon and co-workers used P. A. von Bonsdorff's process for hydrated alumina, and treated a soln. of the hydroxide in soda-lye with freshly precipitated, hydrated oxide, and after washing with water, and drying with acetone obtained a product with $Cr_2O_3.5{\cdot}68H_2O$. B. Schwarz obtained the hydroxide by the hydrolysis of chromites. V. Ipatéeff produced crystals of the hydrated oxide by heating soln. of the salts at high temp. and press. A. C. Becquerel obtained crystals of the hydroxide by suspending a parchment paper tube containing a conc. soln. of potassium aluminate in a soln. of chromic chloride. J. Férée obtained what he regarded as a monohydrate $Cr_2O_3.H_2O$, or $Cr(OH)O$, as a black, amorphous powder by the electrolysis of a neutral soln. of chromic chloride with a platinum cathode. This subject has been previously discussed in connection with R. Bunsen's, and J. Voisin's observations on the electro-deposition of chromium. G. B. Frankforter and co-workers heated a mixture of potassium dichromate and ammonium chloride to 260° and obtained a slate-coloured residue which, on lixiviation with water, left small, greenish-black, iridescent spangles of what has been thought to be a *dihydrate*, $Cr_2O_3.2H_2O$, or $Cr_2(HO)O$.

Analyses of the hydrates of chromic oxide vary very much. According to M. Siewert, the precipitate which has stood for some hrs. in air at 45° for 3 hrs. has $5{\cdot}9\ H_2O$; 3 hrs. at 100°, $5{\cdot}2H_2O$; 4 hrs. at 100°, $4{\cdot}8H_2O$; 2 hrs. at 105°, $4{\cdot}2H_2O$; 2 hrs. at 150°, $3{\cdot}2H_2O$; 5 hrs. at 200°, $2{\cdot}3H_2O$; and 6 days at 220°, $1{\cdot}1H_2O$. L. Schaffner obtained for the ammonia-precipitate dried over sulphuric acid, $6H_2O$; and dried at 100°, $5H_2O$; the alkali-precipitate dried at 100°, $4H_2O$. A. J. W. Forster gave for the air-dried, ammonia-precipitate $Cr_2O_3.8H_2O$. E. Frémy found for the potash-precipitate obtained in the cold, and dried in air, $9H_2O$, and that obtained from a boiling soln., and dried in air, $8H_2O$. J. Lefort, and A. Schrötter obtained similar data. C. F. Cross represented the composition of the precipitate dried at 100° by $Cr_2O_3.4H_2O$, and after standing in air sat. with moisture, $Cr_2O_3.7H_2O$, and after heating to dull redness, $Cr_2O_3.3H_2O$. M. Prud'homme gave $Cr_2O_3.5H_2O$ for the precipitate dried at 100°. G. Wyrouboff gave $Cr_2O_3.8H_2O$ for the precipitate dried over sulphuric acid, and $Cr_2O_3.6H_2O$ when dried at 110°. According to H. Löwel, the red-coloured ammonia-precipitate which dissolves in ammonia forming a red soln. is a different hydroxide from the bluish violet-coloured hydroxide, and this again is different from the green-coloured hydroxide. J. Lefort, E. Frémy, and J. M. Ordway also regarded the differently coloured hydroxides as isomers. According to A. Recoura, chromic hydroxide exists in three different molecular conditions. The first is obtained by precipitating a soln. of either variety of chromic chloride or of any violet chromium salt with an eq. quantity of sodium hydroxide. If treated with hydrochloric acid immediately after precipitation, it combines with 6 mols. of HCl with the development of 41·4 cals. The second variety is obtained by precipitating the oxychloride Cr_2Cl_4O

with 4 mols. of sodium hydroxide. Immediately after precipitation, it combines with 4 mols. of hydrochloric acid only, with development of 24·2 cals. The subsequent addition of a further quantity of 2 mols. of acid produces no thermal disturbance. The third form is obtained when either of the preceding varieties is dissolved in the necessary excess of soda-lye (18 mols. in the first case, 6 mols. in the second), and reprecipitated by neutralizing the excess of alkali. It combines with only 4 mols. of hydrochloric acid, with development of 20·0 cals. A. Colson assumed that there are hydroxides corresponding with the green and violet sulphates. He supposed that the green sulphate corresponded with

$$\begin{array}{c}(\mathrm{OH})_2{=}\underset{\cdot}{\mathrm{Cr}}{-}\mathrm{O}{-}\underset{\cdot}{\mathrm{Cr}}{=}(\mathrm{OH})_2\\ (\mathrm{OH})_2{=}\mathrm{Cr}{-}\mathrm{O}{-}\mathrm{Cr}{=}(\mathrm{OH})_2\end{array}$$

This formulation for hydrated chromic oxide—*i.e.* $Cr_4(OH)_8O_2.10H_2O$, or $Cr_4(OH)_{10}{\cdot}0{\cdot}9H_2O$—was favoured by M. Z. Jovitschitsch. G. Wyrouboff supposed the violet hydroxide is constituted $Cr_2(OH)_6$, and the other hydroxide $Cr_2(OH)_4(OH)_2$, or $Cr_2O(OH)_2$, where the two OH-groups can function as an acid. Although J. J. Berzelius assumed that the oxides precipitated from violet and green soln. of chromic chloride are isomers because they gave the soln. the original colour when dissolved in acids, yet the observations of A. Recoura indicate that the hydrated oxides from differently coloured soln. are the same in chemical structure. The individual variation depends on differences in the physical character of the particles. The rate of precipitation was shown by J. Casthélaz and M. Leune, and H. B. Weiser to have a marked effect on the colour. When slowly precipitated, the oxide is dark green and granular, and when rapidly precipitated greyish-blue and gelatinous. P. Bary and J. V. Rubio found that the dried hydroxide is heterogeneous, for it contains two products. R. Fricke and F. Wever could detect no evidence of crystal structure by X-radiograms.

N. Bjerrum measured the potential of the hydrogen electrode immersed in soln. of chromic chlorides, and inferred that the violet chromic chloride is progressively hydrolyzed, $CrCl_3 \rightarrow CrCl_2(OH) \rightarrow Cr(OH)_2Cl \rightarrow Cr(OH)_3$. He considered that freshly precipitated chromic hydroxide, $Cr(OH)_3$, is a well-defined chemical compound with a solubility product of $4{\cdot}2\times10^{-16}$ at 0° and $5{\cdot}4\times10^{-16}$ at 17°. On the other hand, J. M. van Bemmelen observed that the bluish colloid, prepared by treating a dil. soln. of a chromic salt with ammonia at the ordinary temp. or at 100°, contains originally 11 mols. H_2O; after exposure to the air at 15° it contains 7·8 to 8 mols.; but after keeping for 14 days in an atm. sat. with moisture the quantity of water rises to 13·2 mols., and after exposure to dry air it falls to 7·0 mols. When heated in the air at temp. increasing from 45° to 200°, the amount of water falls from 5·9 to 2·3 mols., and the colour changes to a dirty green. The results obtained on heating at temp. varying from 15° to 100° (i) in a sat. atm., (ii) in ordinary air, and (iii) in dry air, until the weight is constant, show that at every temp. equilibrium is established between the vap. press. of the colloid and that of water at the same temp. At 65° and at 100°, it retains more water in a sat. atm. than at 15° and 65° respectively in a dry atm. After having been heated at from 15° to 100° in dry air, its absorptive power is only slightly diminished, and at higher temp. it retains more water than colloidal silica, alumina, stannic acid or ferric oxide at the same temp., but the higher the temp. to which it has been exposed, the more insoluble it becomes in acids and especially in alkalies. He therefore inferred that colloidal chromic oxide has no definite composition at any temp. between 15° and 280°. This conclusion was confirmed by A. L. Baykoff, and H. B. Weiser. R. Fricke examined the X-radiogram of the hydroxide. S. Veil studied the effect of chromic hydroxide on the decomposition of hydrogen dioxide. H. J. S. King prepared **chromic pentamminohydroxide,** $Cr(OH)_3.5NH_3$, or **chromic hydroxypentamminohydroxide,** $[Cr(NH_3)_5(OH)](OH)_2$, by triturating chromic chromopentamminochloride with moist silver oxide, as indicated by O. T. Christenson. Similar results were obtained by using chromic aquopentamminochloride.

L. Havestadt and R. Fricke studied the dielectric constant. The electrical conductivity, μ mhos, for soln. with a mol of the salt in v litres of water at 0°, and the calculated percentage degree of ionization, α, are :

v . .	22·53	32·85	42·92	65·70	365·8	∞
μ . .	237·8	245·5	250·0	254·1	273·7	283·9
α . .	83·8	86·5	88·1	89·5	96·4	

Hydrated chromic oxide can be obtained in various shades of colour ranging from a clear greyish-blue to a dark green. Some of these are utilized as permanent pigments. The so-called *Guignet's green* has attracted some attention. This vivid, green pigment was prepared by E. Guignet by heating a mixture of potassium dichromate with three times its weight of boric acid, digesting the product with water, and washing it with water. Modifications of the process were described by A. Salvétat, M. Poussier, and A. Scheurer-Kestner ; L. Wöhler and W. Becker, in agreement with A. Scheurer-Kestner, said that boron is without influence on the colour, and that the trace of boron present is derived from the chromium borate first formed and subsequently hydrolyzed. If ammonium dichromate is employed in place of potassium dichromate, not a trace of boron remains after the washing, and when dried at 110°, the product has the composition $2Cr_2O_3.3H_2O$, or $Cr_4O_3(OH)_6$, ascribed to it by A. Scheurer-Kestner, and E. Guignet. A. Salvétat gave $Cr_3O_3.2H_2O$; A. Eibner and O. Hue, $2Cr_2O_3.5H_2O$; and M. Shipton considered it to be a borate, $3Cr_2O_3.B_2O_3.4H_2O$. According to L. Blanc, Guignet's green is not a hydrate, but very finely-divided chromic oxide, which, when heated in air, or treated with chromic acid, forms β-Cr_5O_9. L. Wöhler and J. Dierksen observed that when the green is produced by fusing potassium dichromate with boric acid, the failure to convert the dull olive-green to the brilliant green pigment by heating with water under press. supported the view that the complex $Cr_2O_3.3B_2O_3$ is responsible for the colour, but boric oxide is not a necessary constituent of the bright green. They suggest that the bright green has a gel-structure ; X-radiograms show that a lattice structure is absent. The reduction of the amount of water in chromium hydroxide gels with an increase in the size of particles progressively increases the brilliancy of the product. Boric acid and silicic acid are effective in producing the required flocculation. The vap. press. of brilliant flocculated hydroxides is greater than that of the dull non-flocculated hydroxides of the same water-content. L. Blanc and G. Chaudron found that Guignet's green yields a black oxide, Cr_5O_9, when heated. L. Wöhler and W. Becker said that a green pigment resembling Guignet's green can be obtained by heating the ordinary oxide with water under press. at 180° to 250°. The composition approximates $2Cr_2O_3.3H_2O$. Whilst Guignet's green has a vap. press. of 13 mm. at 75°, 16 mm. at 81°, and 26 mm. at 86°, the greyish-violet chromium hydroxide, which has the same composition, is found to have a vap. press. of only 2 mm., not increasing between 75° and 93·4°. This small vap. press. may result from the presence of moisture. These differences and the difference in colour of the two hydrates are ascribed to isomerism. The greyish-violet hydroxide is converted into its brilliant green isomeride on prolonged heating with water at 250°. H. B. Weiser added that the amorphous, hydrated oxide, obtained by precipitation, loses water continuously, and while it may be possible to dry the pigment under conditions such that the composition may be expressed by a single formula, yet this does not prove that a true hydroxide is formed. There is no evidence of an inversion temp. in the passage from one coloured variety to that of another colour ; and H. B. Weiser observed that when a soln. of chromic chloride is treated with just enough sodium hydroxide for complete precipitation the precipitate obtained at 0° is greyish-blue ; that at 50°, greenish-blue ; that at 100°, bluish-green ; that at 150°, green with a bluish tinge ; that at 200°, clear green ; and that at 200°–325°, bright green. The time of heating was 30 min. except in the last case when the heating occupied 15 hrs. Hence the colour varies continuously from greyish-blue to clear green as the temp. of precipitation rises; this shows that the colours are not due to isomers, but rather to differences in the sizes of the particles, the structure of the mass, and to the amounts of water enclosed under different conditions of formation. As the temp. of precipitation rises, the oxide becomes less gelatinous, less soluble in acids, and less readily peptized by alkalies. For the solubility of chromic hydroxide in alkali-lye, *vide infra*, chromites.

Hydrated chromic oxide freshly precipitated from cold soln. of a chromic salt by an alkali hydroxide or ammonia, is readily soluble in acids, and readily peptized by alkali hydroxides. The hydrated oxide, however, gradually suffers a change in physical character on *ageing*, and it then becomes far less soluble and far less chemically active. The process of ageing is attended by the growth of aggregates of the primary colloidal particles. The velocity of change is accelerated by raising the temp., or by the use of a medium with a slight solvent action. A. Recoura measured the molar heat of soln. in hydrochloric acid with an oxide precipitated by adding an acid to a colloidal soln. in alkali-lye, and kept for definite intervals of time. Thus, the mol. ht. of soln. in cals. of the freshly precipitated oxide is 20·70; when kept 10 min., 19·0 cals.; 1 hr., 5·80 cals.; 2 hrs., 3·90 cals.; 4 hrs., 2·85 cals.; 7 hrs., 2·40 cals.; 1 day, 1·75 cals.; 7 days, 1·20 cals.; 30 days, 0·75 cal.; and 60 days, 0·50 cal. F. Bourion and A. Sénéchal observed that the rate at which hydrated chromic oxide reduces hydrogen dioxide becomes less on standing. The reaction appeared to be quadrimolecular for the first 8 hrs., due, it was supposed, to the transformation of the original oxide into complexes, so that the soluble and insoluble varieties represent definite allotropic forms. R. Fricke and O. Windhausen attributed the ageing to an increase in the size of the particles, and showed that it is not due to dehydration, or to the development of a microcrystalline structure. R. Fricke and co-workers observed no evidence of a crystalline structure in the ageing of hydrated chromic oxide. A. Simon and co-workers studied the vap. press. of the hydrated oxide. The continuous curve, Fig. 17, was obtained with a preparation precipitated by ammonia, washed with water at 60°, then with acetone, and dried in air. Its composition approximated $Cr_2O_3.6{\cdot}68H_2O$. This curve shows a slight flattening with the tri- and mono-hydrate. The other curve is obtained with a specimen precipitated by hydrazine, washed, and dried over sulphuric acid in vacuo for 8 weeks when its ocmposition was $Cr_2O_3.4{\cdot}87H_2O$. The formation of the tri- and mono-hydrates is clearly shown.

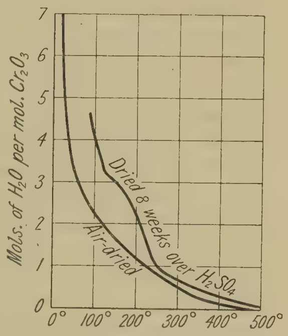

FIG. 17.—The Vapour Pressure of Hydrated Chromic Oxides.

M. Siewert showed that when the hydrated oxide is heated to 200°, in air, it takes up oxygen forming a black powder of variable composition, and it is regarded as a mixture of chromic oxide, chromic anhydride, and water. M. Krüger first observed the tendency of the hydrated oxide to take up oxygen when heated. A. Geuther showed that when the hydrated oxide is deposited on the negative pole, it is liable to form chromic anhydride by taking up oxygen. M. Z. Jovitschitsch found that hydrated chromic oxide readily absorbs carbon dioxide from the atm. forming $[Cr_2(OH)_5]_2CO_3.8H_2O$. The light grey hydrated chromic oxide which is precipitated with small quantities of ammonium hydroxide dissolves in an excess of ammonia to form a ruby-red soln. whose solubility is affected by the presence of ammonium salts. If the red soln. is kept for some time, M. Z. Jovitschitsch observed that violet-blue **chromium diamminohydroxide,** $Cr_2(OH)_6.(NH_3)_2.10H_2O$, is precipitated; it readily absorbs carbon dioxide.

A. Recoura gave for the heat of neutralization of hydrated chromic oxide with hydrochloric acid $\frac{1}{3}Cr(OH)_3=6{\cdot}865$ Cals.; E. Petersen, with hydrofluoric acid, 8·39 Cals.; and M. Berthelot, with sulphuric acid, $\frac{1}{2}H_2SO_4$, 8·22 Cals. W. Pauli and E. Valko studied the conductivity and activity coeff. H. R. Robinson and C. L. Young studied the absorption frequency of the K-series of X-ray spectrum. L. Havestadt and R. Fricke studied the dielectric behaviour of the hydroxide; and H. R. Robinson and C. L. Young, the X-ray absorption frequencies. F. Bourion and A. Sénéchal found that the paramagnetism of an alkaline soln. of chromic oxide diminishes slowly with time, but the diminution is small, and never exceeds 20 per cent. S. Veil found that the magnetic properties of chromic hydroxide are decreased by heating it with water in a sealed tube between 120° and 210°; and another 12 hrs.' treatment has little effect, but when the hydroxide is dissolved in hydrochloric acid, and reprecipitated, the modified magnetism persists and a further change occurs by a similar treatment with hot water. T. Ishiwara found the magnetic susceptibility at 15·7° to be $66·2\times10^{-6}$ mass units, and at $-68·3°$, $110·5\times10^{-6}$ mass units. P. Hausknecht, and E. Wedekind and W. Albrecht observed that the magnetic susceptibility of $Cr(OH)_3$ is greater than that of the corresponding oxide, in agreement with the assumption that the hydroxide is a chemical individual. S. Veil found that the magnetic properties of chromic hydroxide fall to a lower limiting value on repeated precipitation from hot soln.

T. Graham prepared a positive **colloidal solution** of hydrated chromic oxide by peptizing the freshly precipitated oxide with chromic chloride, and dialyzing the liquid to remove the excess of electrolyte. The dark green soln. can be diluted with water or heated, but it is readily flocculated by electrolytes. In continuous dialysis, the diffused liquid was kept at a constant level and not changed during the process, whereas in intermittent dialysis, the diffusate was continuously changed at the rate of 800 c.c. per hour. M. Neidle and J. Barab found that some colloidal particles do diffuse through the parchment membrane; although W. Biltz, and H. W. Fischer and W. Herz observed no such diffusion. In the dialysis of hydrated chromic oxide in a soln. of chromic chloride, the ratio $\frac{1}{3}Cr : Cl$ in the diffusate, with intermittent dialysis, is always greater than unity, and this the more the longer the period of dialysis for the same diffusate. In continuous dialysis, the ratio $\frac{1}{3}Cr : Cl$ in the diffusate increases from unity to a maximum of 1·57, and then gradually diminishes towards zero. In intermittent dialysis, about 6 per cent. of the original colloid is still associated with considerable electrolyte, and it remains in the membrane at the end of 56 days; but the colloid still diffuses so that by continuing the process, the whole of the colloid would be removed from the membrane. In the continuous dialysis, 75 per cent. of the original colloid remains in the membrane. Continuing the process for 35 days increases the purity of the colloid without loss of chromium. If the intervals in intermittent dialysis are made smaller, more satisfactory results are to be expected. In fact, by conducting the entire process in very short intervals, the efficiency may even exceed that of continuous dialysis. The latter procedure is, however, impractical. The variations in the ratio of $\frac{1}{3}Cr : Cl$ in the diffusates are accounted for by the assumption of a gradual growth of the particles. In the intermittent process, the particles do not grow sufficiently to be retained by the membrane, whereas in the continuous process they do. A. Simon and co-workers used the dialyzer recommended by A. Gutbier and co-workers. The process of dialysis was studied by N. Bjerrum by measuring the osmotic press. of the colloidal soln. It is hence calculated that the colloidal chromium particle consists of 1000 chromium atoms and carries 30 free charges. The number of chromic oxide molecules in a colloidal particle is about 240. For complete coagulation the necessary amount of ferrocyanide corresponds exactly with the total charge on the colloid, whilst about 15 per cent. excess of ammonium or potassium sulphate is required. The commencement of coagulation is marked by a sudden break in the curve obtained by plotting conductivity against c.c. of ammonium sulphate. The subject was discussed by A. Lottermoser and W. Riedel, and H. Rinde. R. Wintgen and W. Biltz gave 580 for the number of chromic oxide molecules in a colloidal particle aged by boiling, and 750,000 for the case of an aged ferric oxide colloidal particle. These numbers are of doubtful accuracy. J. R. I. Hepburn found that the product obtained after a prolonged freezing is colloidal in nature, but has some properties usually regarded as characteristic of the crystalline state. J. H. Yoe and E. B. Freyer measured the $H^{\cdot}$-ion conc. and viscosity of hydrosols of chromic oxide; D. N. Chakravarti and N. R. Dhar, the viscosity of the sol in the presence of electrolytes; E. Manegold and R. Hofmann, the permeability of membranes for the hydrosol; and S. Horiba and H. Baba, the effect of light on the osmotic pressure of the hydrosol.

C. Paal prepared a colloidal soln. of hydrated chromic oxide by reducing a soln. of ammonium chromate with colloidal platinum in the presence of sodium protalbinate which acts as a protective colloid. The colloid may be partially purified by dialysis. Soln. of aluminium or ferric salts give a precipitate of hydrated oxide when boiled with sodium acetate; but with chromic acetate soln., H. Schiff, and B. Reinitzer obtained no precipitate when the soln. was boiled; nor was a precipitate obtained in the cold with alkali hydroxide, ammonia, ammonium hydroxide or carbonate, sodium phosphate, or with barium hydroxide or carbonate. Except in the case of sodium phosphate, these reagents give precipitates with boiling soln. There is a slow action between chromic salt and sodium acetate in the cold, for, on standing some time, in the presence of alkali, the colour of the liquid changes and a jelly is formed. In the case of a boiling soln. of hydrated chromic oxide and sodium acetate, the precipitate formed is probably a complex acetate. Iron and aluminium acetates associated with violet chromic acetate do not give a precipitate when boiled or when treated with alkali-lye or aq. ammonia. This, said H. B. Weiser, is not due to peptizing action of the adsorbed hydrated chromic oxide because hydrated chromic oxide is not the primary product of the hydrolysis of chromic acetate, and, as B. Reinitzer has shown, green chromic acetate does not prevent the precipitation of hydrated ferric oxide. The phenomenon as probably the result of the formation of the iron-chromic acetates was studied by R. F. Weinland and E. Guzzmann. The alleged formation of colloidal hydrated chromic oxide, by B. Reinitzer and H. W. Woudstra, by dialyzing soln. of chromic acetate, does not seem right since basic chromic acetates are probably produced. M. Neidle and J. Barab obtained no colloid by dialyzing chromic acetate soln. into which superheated steam was passed; nor was any obtained by the dialysis of a cold soln. of purified chromic chloride, although H. M. Goodwin and F. W. Grover obtained a little by the dialysis of the commercial ferric chlorides. W. Biltz obtained no colloid by the hydrolysis of soln. of chromic nitrate, owing to the small hydrolysis of the salt as observed by H. W. Woudstra. S. Takegami obtained the colloid at the cathode during the electrolytic reduction of chromic acid; and B. Kandelaky, by the hydrolysis of chromic ethylate.

H. W. Fischer studied the solubility of hydrated chromic oxide in a soln. of chromic chloride; R. Wintgen and H. Weisbecker, the amphoteric properties of the colloid; and P. Bary and J. V. Rubio, E. Manegold and R. Hofmann, and R. Wintgen and O. Kühn, the structure of the colloid. F. Haber showed that if the rate of aggregation of a colloidal sol is high, amorphous precipitates are to be expected which gradually, and particularly on warming, pass into the crystalline condition. If, however, the rate of aggregation is depressed by only slightly exceeding the solubility limit, the rate of arrangement may be sufficient to cause the orderly formation of crystals before the formation of visible particles has occurred. This, however, involves an alteration in the rate of aggregation due to electrical phenomena at the boundary of the molecules and liquid, the net result of which is that the growth of the aggregates is greatly impeded and sols are produced.

The colloidal soln. of hydrated chromic oxide prepared as just indicated was shown by W. Biltz, and W. Herz to be a **positive hydrosol** because it migrates to the cathode under the influence of an electrical stress. On the other hand, the green colloidal soln. obtained by adding an excess of alkali hydroxide to a soln. of a chromic salt was found by R. Kremann to be a **negative hydrosol** because, under the influence of an electrical stress, it migrates to the anode. W. Reinders studied the electrophoresis of the colloid. The clear, negative colloidal soln. was found by H. W. Fischer and W. Herz to precipitate spontaneously on standing, particularly if the ratio of chromic oxide to hydroxide is large. This is due to the ageing of the hydrated oxide. A. Hantzsch also observed that owing to ageing, the precipitated and washed chromic oxide is not peptized by alkalies. The colloid is precipitated by adding electrolytes owing to the adsorption of the cations as observed by H. W. Fischer. A. Lottermoser found that the ultra-filtration of the chromic oxide sol peptized with the corresponding chloride gives a filtrate which contains hydrochloric acid of the same $H^{\cdot}$-ion conc. as that of the sol. The mycellia therefore retains the chloride ion whose negative charge compensates the positive charge of the colloidal particles. The conductivity of the sol is greater than that of the ultra-filtrate, and the difference is taken to represent the true conductivity of the mycelles which are regarded as complex electrolytes. A. B. Dumansky and co-workers studied this subject. R. Fricke and co-workers found tetramethylammonium hydroxide to be a strong peptizing agent.

C. F. Nagel, W. D. Bancroft, and N. G. Chatterji and N. R. Dhar showed that the colloidal oxide can be removed by the ultra-filter. W. Biltz and W. Giebel added that the colloidal soln. consists mainly of amicrons, only a small proportion of sub-microns are present. There has been some discussion as to whether the colloidal soln. contains alkali chromite. H. W. Fischer and W. Herz said that peptization, not dissolution, occurs. This is in agreement with hypothesis that the soln. is really the colloidal oxide and the observation of A. B. Northcote and A. H. Church that complete soln. occurs in the presence of 40 per cent. of ferric oxide; 12·5, manganous oxide; or 20 per cent. of either cobalt or nickel oxide, whereas complete precipitation occurs with 80 per cent. of ferric oxide; 60, of manganous oxide; or 50, of either cobalt or nickel oxide. Analogous observations were made by M. Prud'homme, and M. Kreps. H. B. Weiser and G. L. Mack obtained an **organosol** in propyl alcohol.

According to C. F. Nagel, when an excess of potassium hydroxide is added to a soln. containing varied proportions of ferric chloride and chromic sulphate, the iron is not precipitated in presence of excess of the chromic salt, and the chromium is completely precipitated with the iron when the ferric salt is present in considerable excess. It is supposed that these effects are due to mutual adsorption. In a similar way, the hydroxides of manganese, cobalt, nickel, copper, and magnesium are absorbed by colloidal chromic hydroxide, whilst this is also adsorbed and removed from soln. by the above hydroxides when these are present in relatively large quantities. In presence of copper, chromium is not precipitated by ammonia, and it is suggested that this may be due to the presence of colloidal cupric hydroxide, which adsorbs the chromic hydroxide. The peptized soln. gradually settles leaving only a faintly coloured liquid; a collodion filter removes all the hydrated oxide leaving in soln. a little chromic chloride; and peptized hydrated chromic oxide cannot be extracted from soln. with benzene or light petroleum, but it goes into the dimeric interface. J. K. Wood and V. K. Black treated precipitated chromic oxide with varying proportions of a soln. of alkali hydroxide of varying concentration. The presence of chromate in the soln., after two months, indicated that some chromite had been formed; whilst a soln. of chromic chloride treated with a large excess of alkali-lye, after standing two months, gave a colloidal precipitate, and a yellow soln. of chromate formed by oxidation. They concluded that chromites do exist in an alkaline soln. of chromic hydroxide; when the soln. is freshly prepared and is kept a little time, part of the dissolved hydroxide separates out in a less soluble form, and probably does, during this period of transition, exist for a time in the colloidal condition, but when all such precipitation has taken place, a small amount of chromite will still be present in the soln.

According to E. Müller, when an excess of chromic oxide or hydroxide is shaken with aq. soln. of sodium hydroxide for several days, the solubility is dependent on the time of agitation, rising to a maximum and then falling to a constant value. Both the maximum and final solubilities attain their highest values at 14N-NaOH. It is assumed that chromium hydroxide is a "solid-liquid" in which simple and polymerized molecules are present in homogeneous soln. On account of the magnitude of the internal friction, equilibrium is only slowly attained. The ageing process does not so much consist in the enlarging of single particles as in a progressive change during polymerization and is thus essentially chemical in character. H. B. Weiser added that even if chromic oxide does possess slightly acidic properties, not all the oxide is present as chromite; and it is doubtful if any chromite is present when slightly more alkali-lye is present than is needed to precipitate the chromic oxide completely. H. N. Holmes and M. A. Dietrich observed that mercuric sulphide is not precipitated by hydrogen sulphide from a 0·5N-hydrochloric acid soln. containing green chromic chloride and mercuric chloride in excess of the ratio 2 : 1, but is adsorbed by the colloidal chromic hydroxide produced by the hydrolysis of the chloride. The hydrolysis increases on keeping, and after 48 hrs. precipitation does not occur when the above ratio is 1 : 3·5, but this ratio may be depressed by a sufficient concentration of hydrogen or sulphate ions. Thus, chromic sulphate has no influence on the precipitation. The formation of colloidal chromic hydroxide is probably preceded by the conversion of the green chromic chloride into the violet form. The order of the adsorption is reversed by using a large excess of mercuric chloride and precipitating from a hot 0·5N-acid soln. K. C. Sen found that the absorption of acids by chromic oxide can be summarized in Fig. 18.

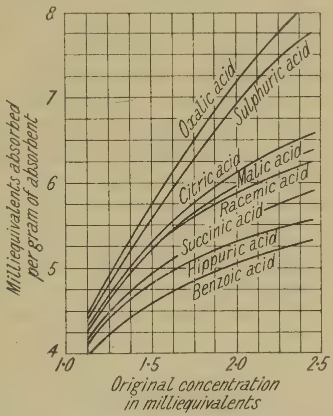

FIG. 18.—The Absorption of Organic Acids by Hydrated Chromic Oxide.

H. B. Weiser reported that the precipitation values for potassium salts for a negative colloidal soln. containing 365 grms. of chromic oxide per litre were for ferricyanide, 0·485 millieq. per litre; chromate, 0·525; dichromate, 0·535; sulphate, 0·550; oxalate, 0·570; iodate, 0·635; bromate, 19·0; chloride, 30·0; bromide, 33·0; chlorate, 33·8; and iodide, 37·5. M. Bjerrum observed that by adding a soln. of 0·1N-ammonium sulphate to a soln. containing 0·112 mols of Cr, and 0·01 mol of nitric acid, the electrical conductivity of the soln. altered as indicated in Fig. 19. E. E. Porter measured the H$^{\cdot}$-ion conc. of a negative colloidal soln. of hydrated chromic oxide containing 2·5 grms. Cr_2O_3 per litre, when 5 c.c. were treated with 15 c.c. of a soln. containing salt and acid. A rapid precipitation of the colloid occurred when the p_H was between 3·5 and 6·0. The flocculation of the colloidal soln. was also studied by A. Miolati and E. Mascetti, and N. Bjerrum, A. Ivanitzkaja and L. Orlova, S. L. Jindal and N. R. Dhar, K. Mohanlal and N. R. Dhar, W. V. Bhagwat and N. R. Dhar, S. Ghosh and N. R. Dhar, K. C. Sen and M. R. Mehrotra, K. C. Sen and N. R. Dhar, and R. Wintgen and H. Löwenthal. H. B. Weiser also studied the flocculation of a colloidal soln. of chromic oxide by mixed electrolytes; and for the precipitation value of a negative colloidal soln.

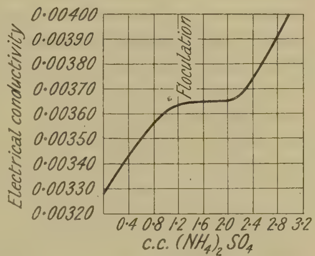

FIG. 19.—The Effect of Ammonium Sulphate on the Flocculation of a Colloidal Solution of Chromic Oxide.

obtained by adding 45 c.c. of $2N$-KOH to 5 c.c. of a soln. of chromic chloride containing 40 grms. of chromic oxide per litre, the result with barium chloride was 5·15 millieq. per litre; potassium chloride, 500·0; sodium chloride, 210·0; lithium chloride, 51·0; sodium sulphate, 315·0; and sodium acetate, 220·0. S. Roy and N. R. Dhar studied the coagulation of the colloid in light. T. Katsurai observed that the hydrosol of chromic oxide does not coagulate like that of ferric oxide when heated under press.

B. Reinitzer prepared a **hydrogel** by boiling a soln. of a chromic salt and sodium acetate, rendered alkaline by alkali-lye or ammonia, and allowing it to set to a jelly. E. H. Bunce and L. S. Finch obtained a jelly by allowing a mixed soln. of alkali-lye and chrome alum to stand. They did not get the jelly by using soln. of chromic sulphate, nitrate, or chloride; but C. F. Nagel obtained the jelly with sulphate by keeping down the conc. of the alkali. H. B. Weiser observed that the rapid addition of a slight excess of alkali-lye to a soln. of chromic chloride produces a negative colloidal soln. which precipitates slowly forming a jelly; if the precipitation is hastened by heating the soln., or by adding a suitable amount of electrolyte, the precipitation is rapid and it is gelatinous but not a jelly; and finally, if the hydrated oxide has been peptized by a large excess of alkali, the precipitate forms slowly and is granular. R. Griessbach and J. Eisele obtained the gel by peptizing the hydrosol. J. Häusler and B. Kohnstein obtained the gel by separately atomizing an acid soln. of chromic acid and an alkaline soln. of sucrose in a mixing chamber, and recovering the colloidal hydroxide. D. N. Chakravarti and N. R. Dhar found that during dialysis of a hydrosol of hydrated chromic oxide, the liquid becomes more viscid and finally gelatinizes. S. Prakash and N. R. Dhar found that the soln. of 4 c.c. $0·5M$-$CrCl_3$, and 8 c.c. of $3·57N$-$CH_3.COONa$, mixed in half an hour with 2 c.c. of $2N$-$(NH_4)_2SO_4$ and 5 c.c. of $2·34N$-NH_4OH added drop by drop, and the soln. made up to 20 c.c., sets to a jelly in 6½ hrs. at 30°. The viscosities of the soln. were:

Age . .	0	30	60	90	120	150 min.
Viscosity .	0·01465	0·01469	0·01527	0·01646	0·01873	0·02208

K. C. Sen and M. R. Mehrotra studied the peptization of chromic hydroxide by arsenious acid; and K. C. Sen, by sugar. S. G. Mokruskin and O. A. Esin examined the adsorption of aniline dyes by chromic oxide; N. Nikitin, the adsorption of ammonia; C. E. White and N. E. Gordon, and E. E. Porter, organic dyes; H. B. Weiser, oxalates; K. C. Sen, benzoic and acetic acids. They found that hydrated chromic oxide adsorbs acids and arsenious acid more than hydrated chromic or ferric oxides adsorbs arsenic trioxide; and N. R. Dhar and co-workers found that various metal salts—Zn, Cd, Co, and Ni—but not Ag salts, are adsorbed. According to E. Toporescu, when chromium is precipitated by ammonia from soln. of its salts containing calcium or magnesium, the amounts of these salts carried down increase with their concentration, and tend towards limits corresponding with the chromites, $Cr_2O_3.3CaO$ and $Cr_2O_3.3MgO$, respectively. The calcium or magnesium may be removed from such precipitates by washing them on the filter or by decantation with a boiling 5 per cent. soln. of ammonium nitrate. H. B. Weiser and E. E. Porter studied the effect of the $H^{\cdot}$-ion conc. of soln. on the adsorptivity of hydrated chromic oxide.

§ 11. Chromites

Hydrated chromic oxide shows pronounced basic properties uniting with acids to form tervalent chromium salts. It is, however, an amphoteric oxide and it acts as a weak base forming salts—**chromites**—which have the spinel formula $RO.Cr_2O_3$, or $R(CrO_2)_2$. These salts can be regarded as **metachromites** derived from **metachromous acid,** $HCrO_2$, or $HO.CrO$; there are also indications of the formation of **orthochromites,** derived from **orthochromous acid,** H_3CrO_3, or $Cr(OH)_3$. According to F. Hein and H. Meininger,[1] chromium triphenylhydroxide $Cr(C_6H_5)_3OH$ is nearly as strong a base as sodium hydroxide. R. Wintgen and H. Weisbecker studied the amphoteric properties of chromic oxide hydrosol.

Z. Weyberg reported crystals of **lithium chromite,** $LiCrO_2$, to be formed along with lithium aluminate when mixtures of an excess of lithium chromate with china clay are calcined. The brown powder consists of microscopic, isotropic, octahedral crystals. As previously indicated, there are differences of opinion as to the nature of the green liquid obtained when freshly precipitated hydrated chromic oxide is treated with alkali-lye. The process is one of either peptization or dissolution ; or else it includes both. R. Kremann, M. Kreps, and J. K. Wood and V. K. Black consider that the soln. of hydrated chromic oxide in alkali is chromite ; while W. Herz and H. W. Fischer, A. Hantzsch, C. F. Nagel, W. V. Bhagwat and N. R. Dhar, and H. B. Weiser consider it to be peptized, hydrated chromic oxide. C. Fricke and O. Windhausen determined the solubility of hydrated chromic oxide approximating $Cr_2O_3.9H_2O$, expressed in grms. Cr_2O_3 per 100 c.c. of soln., after three days' digestion in a soln. of sodium hydroxide at ordinary temp. and obtained the following results :

N-NaOH .	0·5	0·71	5·10	9·89	10·00	11·06	14·15	15·63
Cr_2O_3 .	0·25	0·5	1·58	2·89	2·68	1·90	0·80	0·40
K or K' .	3·6	3·4	3·2	3·4	2·7	2·6	2·3	1·5
	$NaCrO_2$				Na_3CrO_3			

With $17·42N$-NaOH, the soln. was almost colourless, $K=[NaOH]/[Cr]$, and $K'=[NaOH]^3/[Cr]$. The results are plotted in Fig. 20.

According to E. Müller, the equilibrium condition between a soln. of sodium hydroxide and chromic hydroxide is very slowly attained. The curves, Fig. 21, rise to a maximum and then fall to a minimum value, due, it is supposed, to the chromic hydroxide dissolving unchanged in the lye ; it then changes by the loss of water into a less soluble oxide, a change which is accelerated by heat. It is assumed that the equilibrium conditions are: $Cr(OH)_3 + 3NaOH \rightleftharpoons Na_3CrO_3 + 3H_2O$; $Cr(OH)_3 + 2NaOH \rightleftharpoons Na_2HCrO_3 + 2H_2O$; and $Cr(OH)_3 + NaOH \rightleftharpoons NaH_2CrO_3 + H_2O$; followed by $NaH_2CrO_3 + H_2O \rightleftharpoons NaCrO_2 + 2H_2O$. R. Fricke and O. Windhausen studied this subject and found that when hydrated chromic oxide is treated with sodium hydroxide, the formation of chromite precedes the formation of the hydroxide. With sodium hydroxide below 10*N*, primary sodium chromite is formed, whilst above 10*N* the soln. contains also tertiary sodium chromite. Potassium chromite is similarly produced; below 8*N*-alkali only the primary chromite is formed, whilst above 8*N* the soln. contains also secondary chromite. From soln. of potassium chromite which have stood for a long time, needle-shaped crystals of the formula $Cr_2O_3.3K_2O.8H_2O$ have been obtained. R. B. Corey found that the clear supernatant liquor left by chromic hydroxide settling from soda-lye contains no chromium, showing that chromic hydroxide is insoluble in that menstruum, and the apparent solubility is really peptization and not a case of soln. N. Demassieux and J. Heyrovsky inferred that soln. of alkali chromite are not true soln. but contain colloidal chromic hydroxide. The primary **sodium metachromite,** $NaCrO_2$, is formed with alkali-lye below 10*N*-NaOH; and **sodium orthochromite,** Na_3CrO_3, above that conc. J. d'Ans and J. Löffler obtained $NaCrO_2$ by the action of chromic oxide on sodium hydroxide. J. Heyrovsky obtained similar results with potassium hydroxide as those obtained with soln. of sodium hydroxide; below 8*N*-KOH, only **potassium metachromite,** $KCrO_2$, is formed, and above that concentration, **potassium orthochromite,** K_3CrO_3. Z. Weyberg found that by melting mixtures of china clay and alkali chromate, chromic oxide first separates out, and afterwards the chromite. If the soln. of potassium chromite be allowed to stand for a long time, needle-shaped crystals of the tetrahydrate, $K_3CrO_3.4H_2O$, are deposited. These conclusions were confirmed by observations on the f.p., and potential of the soln. M. Kreps could not prepare potassium and sodium chromites in the dry way, because in subsequently washing out the excess of alkali with water, the chromite is decomposed. R. Kremann found that the movements towards the anode of the green soln. of hydrated chromic oxide in conc. alkali-lye demonstrates the existence of chromites; the hydrated chromic hydroxide is not present merely as a colloid because it can diffuse through parchment into the alkaline soln. H. P. Cady and R. Taft found potassium chromite to be insoluble in liquid sulphur dioxide. P. C. Boudault said that potassium ferricyanide oxidizes a soln. of potassium chromite to chromate. The salt is sparingly soluble in acids.

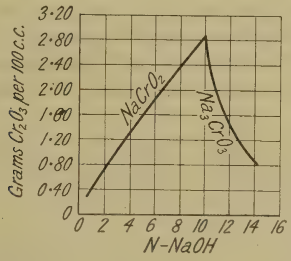

FIG. 20.—The Solubility of Hydrated Chromic Oxide in Solutions of Sodium Hydroxide.

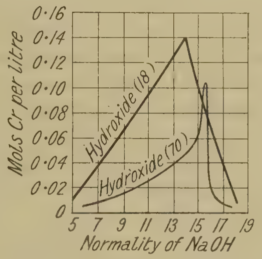

FIG. 21.—The Solubility of Chromic Hydroxide in Solutions of Sodium Hydroxide.

J. F. Persoz obtained **cuprous chromite,** $CuCrO_2$, by calcining cupric chromate in a crucible exposed to the reducing action of the furnace gases, and extracting the product with hydrochloric acid; and L. and P. Wöhler obtained it by heating one of the basic cupric chromites with an excess of cupric oxide above 900°, and extracting the mass with nitric acid of sp. gr. 1·4. Cuprous chromite forms steel-blue or lead-grey triangular plates of sp. gr. 5·237. It is stable in oxygen above 875°, and in air above 770°. It does not oxidize in oxygen at a press. of 1087 mm. at 1020°. It is soluble in nitric acid of sp. gr. 1·4; but a mixture of nitric acid and potassium chlorate oxidizes the chromium to chromic acid. K. Fischbeck and E. Einecke prepared this salt and found that by cathodic polarization in 2 per cent. sulphuric acid, it is oxidized to chromate. L. and P. Wöhler and W. Plüddemann tried the salt as a catalytic agent for oxidizing sulphur dioxide.

J. F. Persoz obtained **cupric chromite,** $Cu(CrO_2)_2$, by heating to redness cupric chromate—L. and P. Wöhler worked above 870°—and extracting the product with hydrochloric acid; L. and P. Wöhler obtained it by heating the cuprous salt in oxygen below 870°, and extracting the mass with nitric acid; they precipitated mixed cupric and chromic hydroxides from a soln. of the mixed sulphates in eq. proportions by means of sodium carbonate, heated the washed product in oxygen at 700°, and then extracted it with dil. acids; C. H. Boehringer treated a soln. of basic cupric chloride with copper tetramminoxide; and M. Gerber heated to redness a mixture of cupric chloride and potassium dichromate, and washed the product first with boiling water, and then with hydrochloric acid. The bluish-black amorphous or crystalline product decomposes slowly at 1000°. If the compound be mixed with cupric oxide, and heated in vacuo, oxygen begins to be given off at 600°. The partial press. of the oxygen is 176 mm. at 779°; 440 mm. at 840°; and 795 mm. at 875°. At 850°, 38 Cals. are needed. The salt is not soluble in dil. acids, or in conc. hydrochloric acid; it is not attacked by sulphur dioxide; but it is oxidized by fused potassium nitrate. F. Wöhler and F. Mahla, and L. and P. Wöhler and W. Plüddemann studied its action as a catalyst in the oxidation of sulphur dioxide.

L. and P. Wöhler and co-workers obtained a basic salt, *cupric oxyoctochromite*, $CuO.4Cu(CrO_2)_2$, by heating commercial cupric chromate, in oxygen at 650°–700°, and extracting the mass with nitric acid. The black product decomposes at 1000°. M. Rosenfeld obtained *cupric trioxychromite*, $3CuO.Cu(CrO_2)_2$, by heating $6CuO.Cr_2O_3.CrO_3$; *cupric hexoxychromite*, $6CuO.Cu(CrO_2)_2$, by heating $7CuO.2CrO_3.5H_2O$; and *cupric tridecoxychromite*, $13CuO.Cu(CrO_2)_2$, by heating $7CuO.CrO_3.5H_2O$; and the acid salt, *cupric hexachromite*, $CuO.3Cr_2O_3$, by heating $CuCr_4O_9.Cr_2O_3.12H_2O$.

According to K. S. Nargund and H. E. Watson, mixtures of calcium and chromic oxides, when heated in vacuo, yield **calcium chromite,** $Ca(CrO_2)_2$; which when treated with acids, yields $CaO.2Cr_2O_3$. Z. Weyberg obtained the same product as prismatic, pleochroic, green needles by melting china clay with a large excess of potassium chromate and calcium oxide. M. Kreps obtained calcium chromite by adding ammonia to mixed soln. of calcium chloride and chrome-alum. F. de Carli said that the reaction between chromic oxide and calcium oxide begins at 550°. M. Gerber prepared calcium chromite by melting a mixture of mol. proportions of potassium dichromate and anhydrous calcium chloride, extracting the mass with water, and washing the product with boiling, conc. hydrochloric acid. E. Dufau obtained it by heating a mixture of chromic and calcium oxides in an electric furnace. K. Fischbeck and E. Einecke prepared this salt by direct sintering of the components. E. Dufau found that the dark olive-green product furnishes a crystalline powder, or pleochroic, prismatic needles, and it has a sp. gr. of 4·8 at 18°, and a hardness of 6. When heated in oxygen, it forms calcium chromate and chromic oxide; the oxidation begins below 100° in air; it is attacked by fluorine, or chlorine when warmed; hydrogen fluoride or chloride attacks it at a red-heat, but hydrofluoric or hydrochloric acid has no action, nor has sulphuric or nitric acid. It is decomposed by molten potassium carbonate, nitrate, or chlorate; Z. Weyberg added that it is slowly attacked by potassium hydrosulphate. T. J. Pelouze prepared **calcium oxychromite,** $CaO.Ca(CrO_2)_2$, by adding potassium hydroxide or ammonia to a mixture of a mol of chrome-alum and 2 mols of calcium chloride; H. Moissan obtained **calcium trioxychromite,** $3CaO.Ca(CrO_2)_2$, in yellow plates, by heating chromium and calcium oxide in an electric furnace ; and E. Dufau, by heating a mixture of chromic and calcium oxides in the electric furnace. It might be added that the pottery colour, emerald green, is prepared by heating chromic oxide with a large proportion of calcium carbonate. A. Mitscherlich obtained **barium chromite,** $Ba(CrO_2)_2$, by heating a mixture of chromic and barium oxides to a white-heat. The crystals are soluble in hydrochloric acid ; and M. Gerber obtained it as a green crystalline powder by melting a mixture of anhydrous barium chloride and potassium dichromate, and washing the cold product with dil. hydrochloric acid. M. Kreps also prepared barium chromite by the action of ammonia on a soln. of chrome-alum and barium chloride. F. de Carli said that the reaction with chromic oxide and barium oxide begins at 220°. E. Dufau obtained **barium octochromite,** $BaO.4Cr_2O_3$, in black, hexagonal crystals of sp. gr. 5·4 at 15°, by heating a mixture of the two oxides in an electric arc-furnace. The product is stable. When heated in oxygen, it forms barium chromate and chromic oxide ; it is slowly attacked when heated with hydrogen fluoride or chloride ; acids are without action ; but it is easily attacked by fused alkali carbonate.

E. Mallard and J. J. Ebelmen melted together beryllium and chromic oxides in the presence of boric oxide, and obtained a dark green powder consisting of crystals of **beryllium chromite,** $Be(CrO_2)_2$. The crystals resemble alexandrite. The so-called *chrome spinel,* $(Mg,Fe)O.(Al,Cr)_2O_3$, from Lherz was called *lherzolite* by J. C. Delamétherie, but it was described earlier by P. Picot de la Peyrouse, and hence the name *picotite.* G. M. Bock, M. Websky, and A. Breithaupt described a related mineral which was called *magnochromite,* or *magnesiochromite—vide infra,* chromite. Analyses of picotite and magnesiochromite were reported by T. Thomson, B. Kosmann, F. Sandberger, A. Damour, A. Hilger, G. C. Hoffmann, C. Friedheim, and T. Petersen. E. S. Simpson proposed the term **picrochromite** —πικρός, bitter, in allusion to the bitter taste of magnesium salts—for members of the spinel-chromite series approaching in composition $Mg(CrO_2)_2$, discussed by T. S. Hunt, T. Petersen, E. Glasser, etc. There are four components, and the end-terms are: (1) *spinel,* $Mg(AlO_2)_2$—including spinel, ceylonite, and magnesiochromite ; (2) *hercynite,* $Fe(AlO_2)_2$—including hercynite and picotite ; (3) *picrochromite,* $Mg(CrO_2)_2$—including picrochromite and chromopicotite or magnesiochromite ; and (4) *chromite,* $Fe(CrO_2)_2$—including chromite, and beresofite. J. J. Ebelmen obtained **magnesium chromite,** $Mg(CrO_2)_2$, by melting a mixture of chromic and magnesium oxide with boric oxide in a porcelain oven, and extracting the product with hydrochloric acid. E. Schweitzer obtained it by calcining potassium magnesium chromate and extracting the residue with dil. and afterwards with hot conc. acid ; K. Fischbeck and E. Einecke, by the sintering of the components ; M. Gerber, by melting a mixture of anhydrous magnesium chloride and potassium dichromate, and extracting the product with hot conc. hydrochloric acid ; W. R. Nichols, by adding an excess of ammonia to a soln. of a mixture of a mol of magnesium sulphate and 1·19 mols of chrome-alum and some ammonium chloride—M. Kreps used a similar process—and E. Dufau, by heating in the electric arc-furnace a mixture of chromic and magnesium oxides. M. L. Huggins showed that the crystals are of the spinel type, and he discussed the electronic structure. S. Holgersson found that the X-radiogram gave for the lattice parameter $a=8{\cdot}32$ A. and the sp. gr. 4·45 ; L. Passerini gave $a=8{\cdot}29$ A., the sp. gr. 4·49, and the vol. of unit cell $569{\cdot}72\times10^{-24}$ c.c. J. J. Ebelmen said that the dark green octahedra have a sp. gr. 4·415 at 15° and scratch glass but not quartz. E. Dufau gave 4·6 for the sp. gr. at 20°, and said that the hardness is greater than that of quartz. F. Beijerinck found that it is a good conductor of electricity ; but it is not magnetic. E. Dufau observed that the compound is not changed when strongly heated ; it is oxidized with difficulty by oxygen at a red-heat ; it is not attacked by chlorine or bromine ; it is attacked with difficulty by hydrofluoric or hydrochloric acid ; J. J. Ebelmen said that it is not attacked by conc. hydrochloric acid. E. Dufau, and E. Schweitzer found that it is easily attacked by hot, conc. sulphuric acid ; it is not attacked by boiling nitric acid; it is insoluble in alkali-lye; and it is slowly attacked by molten potassium nitrate and chlorate—and, added W. R. Nichols, it is slowly oxidized to chromate by fused sodium carbonate and potassium nitrate. W. R. Nichols obtained **magnesium oxychromite,** $MgO.Mg(CrO_2)_2$, by adding an excess of ammonia to a mixed soln. of chrome-alum and an excess of magnesium sulphate. G. Viard obtained it as a pale brown powder, by calcining at a red-heat either magnesium chromate, or potassium magnesium chromate. When further heated it passes into **magnesium oxyoctochromite,** $MgO.4Mg(CrO_2)_2$; if potassium dichromate mixed with magnesium oxide be heated to redness, **magnesium oxytetrachromite,** $MgO.2Mg(CrO_2)_2$, is formed. According to M. R. Nayar and co-workers, magnesium chromate decomposes at 650°, forming chromites from which the magnesium oxyoctochromite, $MgO.4Mg(CrO_2)_2$, can be obtained as an insoluble residue after extraction with hydrochloric acid; a mixture of equimolar proportions of magnesia and chromic oxide above 600° yields **magnesium oxydecachromite,** $MgO.5Mg(CrO_2)_2$. W. R. Nichols prepared **magnesium tetrachromite,** $MgO.2Cr_2O_3$, by adding ammonia to a mixed soln. of a mol of magnesium sulphate and 2·02 mols of chrome-alum.

J. J. Ebelmen prepared **zinc chromite,** $Zn(CrO_2)_2$, by the method used for the magnesium salt; M. Gerber, by heating a mixture of anhydrous zinc chloride and an excess of potassium dichromate; G. Chancel, and M. Gröger, by adding potassium hydroxide to a mixed soln. of equimolar parts of a zinc and a chromic salt; and G. Viard, by passing the vapour of zinc chloride in a current of nitrogen or carbon dioxide over heated potassium chromate, and washing the mass with water, and conc. hydrochloric acid. K. Fischbeck and E. Einecke made it as in the case of the magnesium salt. M. L. Huggins showed that the crystals are of the spinel type and he discussed the electronic structure. According to J. J. Ebelmen, the black octahedral crystals have a sp. gr. 5·309, and they are harder than quartz. G. Viard gave 5·29 for the sp. gr. at 13°. L. Passerini calculated 4·436 for the sp. gr. from the lattice data; and found the lattice has the side a=8·280 A.; S. Holgersson gave a=8·323 A. W. Biltz and co-workers discussed the mol. vol. E. W. Flosdorf and G. B. Kistiakowsky examined a mixture of chromic and zinc oxides as a catalyst.

M. Gröger prepared violet-brown *zinc pentoxyhexachromite,* $5ZnO.3Zn(CrO_2)_2$, by heating potassium zinc chromate, and extracting the product with water; G. Viard obtained *zinc oxydichromite,* $ZnO.Zn(CrO_2)_2$, by calcining ammonium zinc chromate; *zinc oxytetrachromite,* $ZnO.2Zn(CrO_2)_2$, by calcining a mixture of zinc chloride and potassium chromate; and *zinc oxydecachromite,* $ZnO.5Zn(CrO_2)_2$, by calcining at a red-heat a mixture of zinc oxide and potassium dichromate.

G. Viard obtained **cadmium chromite,** by passing the vapour of cadmium chloride, in a current of nitrogen or carbon dioxide, over potassium chromate at a white-heat; also by heating cadmium chromate to dull redness, or likewise by heating a mixture of cadmium oxide and potassium dichromate. K. Fischbeck and E. Einecke made it as in the case of the magnesium salt. M. L. Huggins showed that the crystals are of the spinel type and he discussed the electronic structure. S. Holgersson gave a=8·60 A. for the lattice parameter, and 5·84 for the sp. gr. According to G. Viard, the black, octahedral crystals have a sp. gr. of 5·79 at 17°; they scratch glass but not quartz; and they are stable in acids.

L. Passerini found that chromic oxide forms a series of solid soln. when it is heated with alumina, but no **aluminium chromite** is formed; the lattice constants of the solid soln. range from a=4·950 A. for Cr_2O_3 to 4·740 A. for Al_2O_3, and c=6·806 A. to 6·478 A. S. Veil heated compressed mixtures of ceric and chromic oxides, and determined the electrical conductivities and coeff. of magnetization of the mixtures. The resulting curves indicated the existence of **ceric dichromite,** $CeO_2.Cr_2O_3$; **ceric tritoctochromite,** $3CeO_2.4Cr_2O_3$; **ceric tetrachromite,** $CeO_2.2Cr_2O_3$, or $Ce(CrO_2)_4$; and **ceric decachromite,** $CeO_2.5Cr_2O_3$; and the probable existence of **ceric pentitadichromite,** $5CeO_2.Cr_2O_3$; **ceric heptitoctochromite,** $7CeO_2.4Cr_2O_3$; and

ceric octodecachromite, $CeO_2.9Cr_2O_3$. G. Chancel mixed alkaline soln. of lead and chromic oxides, and obtained a green precipitate of **lead chromite,** $Pb(CrO_2)_2$. S. H. C. Briggs obtained **antimony oxychromite,** $2Sb_2O_3.Cr_2O_3$, by heating 3·5 grms. of antimony oxychloride, $2SbOCl.Sb_2O_3$, with 8 grms. of chromic trioxide and 8 c.c. of water in a sealed tube for 5 hrs. at 200°. The brown powder was thoroughly washed and dried. It was insoluble in alkali-lye, water, acids, and aqua regia. S. H. C. Briggs heated a mixture of 5 grms. of bismuth oxychloride, 6 grms. chromic trioxide, and 6 c.c. of water in a sealed tube at 200° for 5 hrs. The brown product, **bismuth oxychromite,** $3Bi_2O_3.2Cr_2O_3$, resembled antimony oxychromite. For **tungstic chromite,** *vide infra,* chromium tungstate. C. F. Rammelsberg obtained what was thought to be a yellowish-brown precipitate of **uranium chromite** mixed with chromate by treating uranium tetrachloride with potassium chromate.

J. J. Ebelmen obtained **manganese chromite,** $Mn(CrO_2)_2$ by heating a mixture of manganous and chromic oxides and boric oxide in a porcelain oven, and washing the product with hot, conc. hydrochloric acid. K. Fischbeck and E. Einecke made it as in the case of the magnesium salt. M. Gerber obtained it by melting a mixture of anhydrous manganese chloride and potassium dichromate. M. L. Huggins showed that the crystals are of the spinel type and he discussed the electronic structure. J. J. Ebelmen found that the iron-grey, octahedral crystals have a sp. gr. of 3·87. S. Holgersson gave for the space-lattice a=8·487 A. J. J. Ebelmen found that the crystals scratch glass ; they resist attack by acids, and are oxidized by molten potassium hydroxide and potassium nitrate—*vide infra,* manganese chromate.

The discovery of **ferrous chromite,** $Fe(CrO_2)_2$, or $FeO.Cr_2O_3$, by L. N. Vauquelin[2] has been previously discussed. The occurrence and some analyses of the mineral have also been indicated.

Analyses have been reported by H. Abich, E. Bechi, E. Berthier, G. M. Bock, J. C. Booth and C. Lea, L. H. Borgström, A. Christomanos, F. W. Clarke, E. Divers, L. Duparc and S. P. de Rubies, T. H. Garrett, A. Hilger, A. Hofmann, G. C. Hofmann, K. von John and C. F. Eichleitner, M. Z. Jovicic, E. Kaiser, A. Knop, F. Kovar, H. E. Kramm, A. Lacroix, A. Laugier, A. Liversidge, W. G. Maynard, G. P. Merrill, A. Moberg, H. Pemberton, T. Petersen, J. H. Pratt, G. T. Prior, C. F. Rammelsberg, L. E. Rivot, F. Ryba, H. Seybert, E. V. Shannon, E. S. Simpson, J. L. Smith, W. Tassin, H. Traube, G. Tschermak, F. W. Voit, T. Wada, W. Wallace and R. M. Clark, M. Websky, and A. E. V. Zeally.

The formula was discussed by C. F. Rammelsberg, P. Niggli, E. S. Simpson, N. Federowsky, and A. Lacroix. L. W. Fisher found that pure chromite has been found only in meteorites ; with other varieties there is a wide variation in the proportions of acid and base. Nearly all the chromites which have been analyzed show one or more oxides in excess. This may be due to incomplete separation of chromite and gangue. Consequently, its composition can seldom be represented by a definite formula. Chromite is a member of the spinel family, but all the family cannot be represented in definite isomorphous series.

The mineral was called *iron-chrome,* or rather *Eisenchrom* by P. Meder, and D. L. G. Karsten ; *siderchrom,* by J. J. N. Huot ; *chromoferrite,* by E. J. Chapman ; and **chromite,** by W. Haidinger. Although the composition approximates $Fe(CrO_2)_2$, the iron may be in part replaced by magnesium to form *magnochromite* or *magnesiochromite* (*q.v.*), specimens of which were described by A. Breithaupt, M. Websky, and G. M. Bock. Some of the chromium may be replaced by aluminium and by ferric iron as in the *chromopicotite* from the Dun Mt., New Zealand, described by T. Petersen. Chromite thus merges by gradations into spinel—*e.g. picotite.* A. Lacroix described a black mineral from Madagascar to which he gave the name *chromohercynite,* and its composition approximated $Fe(CrO_2)_2.(Fe,Mg,Mn)(AlO_2)_2$, and its sp. gr. 4·415. According to H. Arsandaux, the chromite of Mow Djeti, Togo, is a *chromiferous ferropicotite,* $(Mg,Fe,Mn)O.(Cr,Al,Fe)_2O_3$. The *mitchellite* of J. H. Pratt can be represented by $(Fe,Mg)O.(Cr,Al)_2O_3$. The mineral *chromitite* obtained by M. Z. Jovicic from Western Siberia is possibly a mixture of chromite and magnetite. The incomplete analysis corresponds with $Fe_2O_3.Cr_2O_3$, but ferric and ferrous oxides are not distinguished in the analysis. The sp. gr. is 3·1. H. Forestier and G. Chaudron found that ferric and chromic oxides form solid soln.

The special occurrence of chromite was discussed by A. Arzruni, E. Berwerth, E. Cohen and E. Weinschenk, L. Colomba, J. S. Diller, C. Doelter, E. von Federoff and W. Nikitin, L. Cascuel, A. C. Gill, S. G. Gordon, H. S. Harger, R. Helmhacker, V. Hilber and I. Ippen, F. C. Hochstetter, C. Hütter, E. Kaiser, P. Kato, J. H. Lewis, A. Liversidge, L. F. Lubogetzky, R. W. E. MacIvor, H. B. Maufe and co-workers, M. P. Melnikoff, A. Michel-Lévy, J. H. Pratt, A. Rocati, B. Simmersbach, E. V. Shannon, A. Stella, O. Stutzer, P. A. Wagner, W. Wallace and R. M. Clark, O. Weiss, H. E. Williams, F. Zirkel, etc.—*vide supra*, the occurrence of chromium.

The origin of chromite was discussed by B. Baumgärtel, F. Beyschlag and co-workers, C. Camsell, A. Himmelbauer, A. de Launay, J. H. Pratt, F. Ryba, G. M. Schwartz, E. Sampson, L. W. Fisher, F. E. Keep, C. S. Ross, J. T. Singewald, J. H. L. Vogt, and P. A. Wagner. The occurrence of chromite in meteorites was described by E. Cohen, A. Daubrée, A. Eberhard, L. Fletcher, H. B von Foullon, W. Haidinger, O. W. Huntington, G. F. Kunz, A. Laugier, N. S. Maskelyne, C. F. Rammelsberg, G. Rose, C. U. Shepard, J. L. Smith, F. Stromeyer, G. Tschermak, T. N. Tschernyschoff, R. D. M. Veerbeck, V. Wartha, and F. Wöhler.

J. J. Ebelmen obtained black octahedral crystals by heating in a porcelain oven a mixture of chromic and ferric oxides, tartaric acid, and boric oxide; S. Meunier, by heating a mixture of iron filings, ferrous carbonate and potassium dichromate, or a mixture of alumina, colcothar, chromic oxide, and cryolite, or a mixture of chrome oxide, ferrous chloride, in a crucible lined with cryolite; and M. Gerber, by melting a mixture of anhydrous ferrous chloride and potassium dichromate. Chromite was also prepared by J. A. Hedvall, and K. Fischbeck and E. Einecke, by heating an intimate mixture of the component oxides; and by S. Meunier, by heating chlorides of iron and chromium in hydrogen, and afterwards in steam. J. H. Pratt found a peridotitic magma, containing an excess of magnesia, and a little aluminium and chromic oxides, in which crystals of chromite were present; and J. H. L. Vogt observed that chromite and picotite seem to separate first from such magmas. J. Clouet, and F. Fouqué and A. Michel-Lévy described crystals of a product with crystals like those of chromite, but with the composition **ferrous oxychromite,** $FeO.Fe(CrO_2)_2$; they were obtained by adding ammonia to a mixed soln. of iron and chromium sulphates, and heating the precipitate with borax. C. Sandonnini observed that no ferrite is formed when a mixture of ferrous and chromic hydroxides is oxidized.

Chromite commonly occurs in granular or compact masses of an iron-black or brownish-black colour, which, according to J. Thoulet, may be yellowish- or brownish-red when viewed by transmitted light in thin sections. Chromite also occurs in octahedral crystals described by E. Hussak. J. Königsberger proved that the crystals are isotropic. G. Sukkow found some crystals twinned according to the spinel law; and A. Knop observed some chromite crystals with growths of rutile and zircon. Ferrous and magnesium chromites form solid soln.; so also do ferrous chromite and ferrous aluminate. There is also evidence that some ferrites and chromites form solid soln. L. W. Fisher found that members of the spinel family are not always isomorphous, but that these series are so: (i) spinel, magnochromite, and chromite; (ii) magnetite, kreittonite, dysluite, and jahrite; (iii) spinel, magnesioferrite, and magnetite; and (iv) gahnite, spinel, and franklinite. P. F. Kerr studied the X-radiograms; and P. E. Wretblad, and L. Passerini found that ferric and chromic oxides furnish a complete series of solid soln. with cells having axial ratios and densities which are linear functions of the composition. The subject was discussed by G. Grenet. L. Tokody found that the cubic lattice of chromite has a=8·05 A., and eight mols. per unit lattice; and S. Holgersson gave

a=8·319 A. P. Niggli discussed the lattice structure which is taken to be that of the spinels—*vide* magnetite. H. Schneiderhöhn discussed the microstructure of polished sections of the mineral. L. W. Fisher said that the colour of these sections corresponds roughly with the chemical composition. With a low proportion of chromic oxide as in picotite, the colour is yellowish-brown; and with a high proportion of chromic oxide the colour is deep cherry-red or coffee-brown. Anastomosing black, opaque lines traversing translucent grains are due to the presence of a foreign substance present either as a solid soln., or deposited as a cement along narrow or incipient fractures. The sp. gr. of the mineral ranges from 4·1 to 4·9; E. F. Harroun and E. Wilson gave 3·88 to 4·15. J. J. Ebelmen's artificial chromite had a sp. gr. of 4·97—*vide infra.* The less the proportion of iron, the smaller the sp. gr., and the harder the mineral on the octahedral face. The hardness is about 5·5. P. J. Holmquist obtained the following results for the cutting hardness on the octahedral faces when the hardness of quartz is 1000. The hardnesses of the samples with an asterisk are mean values for all the faces.

Sp. gr. . .	3·6	3·2	3·6	4·116	4·283	4·283
Hardness .	1779	1621	1531*	1232*	1031*	806*

The hardness decreases from that spinel proper, $Mg(AlO_2)_2$, as the proportion of iron and chromium increases. Y. Tadokoro found the coeff. of thermal expansion and sp. gr. of chromite bricks to be:

	20°	100°	250°	500°	750°	950°
Sp. gr. . .	2·982	2·978	2·966	2·945	2·925	2·910
Coeff. expansion	—	$0{\cdot}0_570$	$0{\cdot}0_597$	$0{\cdot}0_590$	$0{\cdot}0_588$	$0{\cdot}0_590$

The thermal expansions of chromite from different sources, between 20° and 1000°, in oxidizing and reducing atm., were:

	Oxidizing.	Reducing.
Rhodesian	$7{\cdot}29\times10^{-6}$	$17{\cdot}45\times10^{-6}$
African	$8{\cdot}51\times10^{-6}$	$39{\cdot}01\times10^{-6}$
Grecian	$8{\cdot}32\times10^{-6}$	$10{\cdot}06\times10^{-6}$
Indian	$7{\cdot}29\times10^{-6}$	$15{\cdot}91\times10^{-6}$

F. H. Norton gave for the thermal conductivity:

	200°	400°	600°	800°	1000°	1200°	1400°
Heat conductivity .	0·0034	0·0037	0·0039	0·0040	0·0040	0·0041	0·0041

H. Kopp found the sp. ht. of chromite to be 0·159 between 16° and 47°. E. D. Clark, and G. Spezia found that chromite fuses in the oxyhydrogen flame. A. Brun found samples of chromite with m.p., respectively, 1670° and 1850°. C. Doelter considered these results too high and gave 1450° for the m.p. of a sample from Kraubath and added that the mineral was liquid at 1600°. The m.p. of the mineral naturally depends on the proportion of iron, etc. E. S. Larsen found the index of refraction to be 2·08 to 2·10. W. W. Coblentz observed that the ultra-red reflecting power of chromite is uniformly 4 per cent. between wave-lengths 1μ and 11μ. A. de Gramont studied the spark spectrum. W. T. Wherry found chromite to be a good radio-detector. T. W. Case said that chromite is a poor electrical conductor, and the conductivity is not affected by exposure to light. K. Fischbeck and E. Einecke found the resistance to be about 22×10^4 ohms. R. D. Harvey studied this subject. Chromite is not magnetic, but it may appear to be magnetic if contaminated with magnetite. E. F. Herroun and E. Wilson gave 79×10^{-6} mass units for the magnetic susceptibility; and F. Stutzer and co-workers gave 244×10^{-6} units for the coeff. of magnetization. H. A. J. Wilkens and H. B. C. Nitze discussed the magnetic separation of chromite. E. von Federoff observed pseudomorphs of hæmatite after chromite. According to E. Zalinsky, acids are without action on chromite; finely powdered magnetite was dissolved by hydrofluoric acid under conditions where chromite was not attacked. On the other hand, G. Piolti said that 200 c.c. of sulphuric acid, mixed with an equal vol. of water, dissolved 13·42 per cent. of chromite in about 56 hrs.; and a soln. of oxalic acid in the same time formed a green soln. Y. Kato and R. Ikeno discussed the processes for decomposing chromite.

R. J. Elliot obtained dark green **cobalt chromite,** $Co(CrO_2)_2$, by precipitating a mixed soln. of equimolar parts of chrome-alum and cobalt chloride by sodium carbonate. The product is non-magnetic. G. Natta and L. Passerini obtained cobalt chromite and found that the length of unit cell of the spinel type is $a=8{\cdot}31$ A.; the vol. is 574×10^{-24} c.c.; and the sp. gr. 5·14. J. A. Hedvall heated a mixture of cobalt and chromic oxides and obtained octahedral crystals of cobalt chromite which are but little attacked by acids. K. Fischbeck and E. Einecke prepared cobalt chromite by sintering a mixture of the component oxides; and similarly also with **nickel chromite,** $Ni(CrO_2)_2$. R. J. Elliot also obtained nickel chromite by a process analogous to that used for the cobalt salt. The greyish-green nickel chromite is non-magnetic. S. Veil found that the magnetization coeff. of mixtures of the constituent oxides show maxima corresponding with the pure chromites.

§ 12. Intermediate Chromium Oxides

A number of oxides, with compositions intermediate between those of chromic oxide, Cr_2O_3, and chromic anhydride, CrO_3, has been reported. These oxides include Cr_5O_9, Cr_3O_5, Cr_3O_6, Cr_5O_{13}, Cr_5O_{12}, and Cr_6O_{15}. They are sometimes represented as *chromium chromates*. Their individuality is not well established. K. Honda heated chromium trioxide in an apparatus recording the losses in weight in terms of the movement of an indicator on a scale. There is first the expulsion of moisture, and, at about 300°, Cr_6O_{15} is formed; then, at 420°, Cr_5O_9; and, at about 450°, chromic oxide, Cr_2O_3. The results agree with the magnetic observations of K. Honda and T. Sone,[1] who found that at about 280°, Cr_6O_{15} is formed and at 420°, Cr_2O_3; while between 300° and 400°, the strongly paramagnetic Cr_6O_{15}, and the ferromagnetic Cr_5O_9 are present as a mixture. A. Simon and T. Schmidt could not obtain these oxides. They observed only two intermediate oxides, as illustrated by Fig. 22, namely, **chromium pentitatridecoxide,** Cr_5O_{13}, and chromium pentitadodecoxide, Cr_5O_{12}. The other intermediate oxides reported in the literature either do not exist or are too unstable to appear under these conditions.

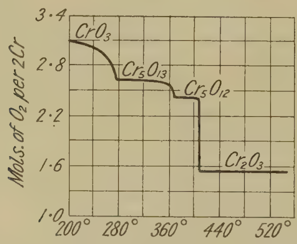

FIG. 22.—Losses in Weight on Heating Chromium Trioxide.

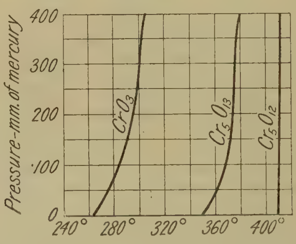

FIG. 23.—Dissociation Pressure Curves of the Chromium Oxides.

The first member, **chromium pentitenneaoxide,** Cr_5O_9, or $2Cr_2O_3.CrO_3$, was obtained by F. Wöhler by passing the vapour of chromyl chloride through a tube at a temp. between 300° and dull redness. If the temp. be too high, free chromic oxide is formed; and A. Geuther and V. Merz said that if it be too low, free chromic anhydride will be present. A. Geuther and V. Merz also obtained a small yield of this oxide by heating chromic anhydride alone, or in a current of oxygen. According to O. Popp, an *enneahydrate*, $2Cr_2O_3.CrO_3.9H_2O$, is produced as a brown mass when a soln. of sodium thiosulphate, with potassium dichromate is boiled. E. Kopp said that this product is the Cr_8O_{15}-oxide. According to L. Blanc, if precipitated chromic oxide, α-Cr_2O_3, be heated to 230° for some time it passes into chromium dioxide, CrO_2, and if this product be hydrolyzed, it forms amorphous or α-Cr_5O_9; and if this product be heated between 350° and 400°, it forms a mixture of crystalline or β-Cr_5O_9, and β-Cr_2O_3. At 450°, this reaction is instantaneous with the evolution of much heat. At 300°, the reaction $2\alpha\text{-}Cr_5O_9+O_2\rightarrow 10CrO_2$ occurs; and at 350°, $10CrO_2\rightarrow 2Cr_5O_9+O_2$. According to L. Blanc, if a salt of tervalent aluminium, iron, or chromium be added to a soln. of a neutral chromate, and the precipitate be washed with boiling water, yellow aluminium chromate, $2Al_2O_3.CrO_3$; or brown ferric chromate, $2Fe_2O_3.CrO_3$; or brown chromic chromate, $2Cr_2O_3.CrO_3$, is formed as the case may be. It is therefore inferred that the pentita-enneaoxide is a chromic chromate. L. Blanc and G. Chaudron assumed that there are two forms of Cr_5O_9 with a transition temp. at 440°—*vide supra*, chromic oxide. A. Geuther and V. Merz observed that the Cr_5O_9-oxide furnishes rhombic prisms paler in colour than chromic oxide, and having a violet tinge. The sp. gr. is 4·0 at 10°; and they considered that F. Wöhler's amorphous, black powder was probably the impure oxide. F. Wöhler said that the compound is magnetic, but, added E. Wedekind and K. Fetzer, not so magnetic as manganese phosphide. While F. Wöhler thought the magnetic oxide of chromium is Cr_3O_4; A. Geuther and V. Merz, Cr_5O_9; and I. Schukoff, Cr_4O_9, L. Blanc showed that the magnetic oxide is probably an unstable variety of Cr_5O_9 intermediate between the α- and β-forms. The magnetic susceptibility with between 0 and 200 gauss is nearly equal to that of magnetite. K. Honda and T. Sone gave for the magnetic susceptibility, χ, with a field of strength H gauss:

H . . .	294	646	1306	2012	3064	6682	9260
χ . . .	718	640	487	408	300	137	99

According to I. Schukoff, the intermediate oxides obtained by heating chromyl chloride or chromic anhydride are magnetic or not, according to the conditions. If the decomposition is controlled so that the temp. does not rise above 500°, the oxides obtained are only feebly magnetic. On heating, however, to 500°–510°, 13–14 per cent. of oxygen is evolved, and the black mass, which has the composition $2CrO_3.Cr_2O_3$, is strongly magnetic. An oxide of the same composition, but prepared at 450°, was very feebly magnetic. A crystalline magnetic oxide was obtained by the decomposition of chromyl chloride; when ignited, it loses only 3·4–4 per cent. of oxygen. According to F. Wöhler, the Cr_5O_9-oxide is reduced to chromic oxide when heated in hydrogen; and when heated in air, it forms green chromic oxide, and is then no longer magnetic. A. Geuther and V. Merz also found that the oxide is slowly reduced to chromic oxide when heated in air; it is insoluble in hydrochloric and nitric acids, in aqua regia, and in a mixture of nitric and hydrofluoric acids; boiling alkali-lye slowly decomposes it into chromic oxide and chromic anhydride; and it is easily decomposed by fused alkali hydroxides.

According to M. Traube,[2] when chromic anhydride is exposed on a glass plate, it dries to a brown crust which is insoluble in water, and adheres strongly to the glass. Its composition agrees with **chromium octitapentadecaoxide**, Cr_8O_{15}, or $2Cr_2O_3.3CrO_3$; and it is supposed to be produced by the action of the dust in the air. It can be obtained by treating a moderately dil. soln. of chromic acid at ordinary temp. with an excess of alcohol, and heating the mixture after the evolution of aldehyde has ceased. Part of the oxide settles quickly and part remains in suspension for some weeks. The precipitate is boiled until the smell of acetic is evident, then agitated with water, and lastly with alcohol until nothing is dissolved out by either liquid. The dried product is a greenish-brown powder; before drying, the product is readily dissolved in hydrochloric and nitric acids, and alkali-lye, but less readily in acetic acid. Ammonia precipitates hydrated chromic oxide from the soln. in acids. A. Simon and T. Schmidt observed that when $Cr_8O_{15}.nH_2O$ is heated, water and oxygen are simultaneously given off between 100° and 400°. The brown powder obtained by C. F. Rammelsberg by mixing soln. of chrome-alum and potassium dichromate was considered to be the *enneahydrate*, $2Cr_2O_3.3CrO_3.9H_2O$; but C. W. Eliot and F. H. Storer showed that it is probably a mixture.

L. N. Vauquelin[3] prepared brown oxide of chromium, or **chromium dioxide,** $Cr_2O_3.CrO_3$, or Cr_2O_4, or CrO_2, or *chromyl chromate*, $(CrO)_2CrO_4$, by heating chromic nitrate until all the nitric acid is expelled, repeating the treatment with nitric acid, and finally heating the product short of redness; F. Brandenburg employed a similar process. M. Z. Jovitschitsch heated the nitrate to 290°; and L. Blanc heated amorphous chromic oxide to 280°—*vide supra.* A. Maus added that the temp. required to expel all the nitric acid results in the formation of chromic oxide. The product obtained by heating hydrated chromic oxide below redness, in air—to 200°–250°, according to H. Löwel—is, according to M. Krüger, chromium dioxide but C. W. Eliot and F. H. Storer, and M. Siewert said that this product is only a mixture. H. Moissan, and W. Manchot prepared this oxide by heating hydrated chromic oxide to 330°–440° in a current of oxygen; M. Z. Jovitschitsch said that anhydrous chromium chromate cannot be prepared by heating the hydrated oxide since decomposition occurs before the last mol. of water is expelled. G. N. Ridley obtained it by heating chromic anhydride to 250°; by passing sulphur dioxide over heated chromic anhydride; and by gently heating a mixture of chromic anhydride and phosphorus in a crucible until all takes fire. E. Moles and F. Gonzalez prepared the dioxide by heating ammonium dichromate to 225°; and E. Maumené, by heating ammonium chromate to 204°.

A number of hydrates of chromium dioxide has been reported. According to C. W. Eliot and F. H. Storer, the compound is not produced by boiling an aq. soln. of ammonium chromate; nor as indicated by L. N. Vauquelin, and H. Moser, by passing chlorine through a soln. of a chromic salt, and precipitating with potash-lye; nor, as indicated by H. Schiff, by treating hydrated chromic oxide, or violet chromic chloride with bleaching powder. K. Seubert and J. Carstens assumed that chromium dioxide is formed as an intermediate stage in the reduction of chromic anhydride by an iodide, or by hydrazine; but R. Luther and T. F. Rutter preferred the assumption that the reduction proceeds through stages involving sexi-, quinque-, quadri-, and ter-valent chromium. The reaction was also discussed by W. L. Miller. According to A. Maus, hydrated chromium dioxide is formed by digesting hydrated chromic oxide with a soln. of chromic acid—not in excess. A. Maus obtained it by digesting a hot soln. of potassium chromate with chromic chloride, A. Bensch, with chromic sulphate, and C. W. Eliot and F. H. Storer, with chrome-alum. E. Schweitzer, P. Grouvelle, and C. W. Eliot and F. H. Storer treated a soln. of potassium dichromate with nitric oxide; O. Popp, and E. Kopp, with sodium thiosulphate; G. N. Ridley, with stannous chloride; A. Vogel, and L. Godefroy, with alcohol; J. W. Swan, with organic substances; and H. Schiff, with oxalic acid. T. E. Thorpe obtained it by treating a soln. of chromium hexoxydichloride with ammonia. P. A. Meerburg found that colloidal chromium dioxide is formed when a soln. of chromic acid is treated with potassium iodide. The colloid is slowly modified with a decreased absorptive power. The amount of water absorbed over conc. sulphuric acid at ordinary temp. is greater than at 100°. A rise of temp. over 100° increases the loss of water, and decreases the absorptive power.

According to A. Vogel, the product dried at 100° is the *dihydrate*, $CrO_2.2H_2O$, while L. Godefroy represented it as a *hemitrihydrate*, $CrO_2.1\frac{1}{2}H_2O$, which he symbolized $(HO)_3{\equiv}Cr-O-Cr{\equiv}(OH)_3$. W. M. Horton found that by heating ammonium dichromate in air below 190° a *hemihydrate*, $2CrO_2.H_2O$, is formed as a black powder. J. J. Berzelius supposed the brown oxide prepared by L. N. Vauquelin to be a definite oxide; T. Thomson, and J. M. Godon de St.

Menin seem to have regarded it as a mixture of chromic oxide and chromic anhydride; and J. F. John, C. W. Eliot and F. H. Storer, J. W. Döbereiner, and A. Maus, as a feeble compound of green chromic oxide and chromic acid—namely, chromium chromate. According to M. Z. Jovitschitsch, when a soln. of chromic oxide in nitric acid is evaporated until excess of acid is removed and the residue is dissolved in water and treated with ammonia, a dark brown, almost black product is obtained, analyses of which are in agreement with the formula, $Cr_2(OH)_8.H_2O$, or $CrO_3.Cr_2O_3.7H_2O$. The loss of $1H_2O$ over sulphuric acid, of $2H_2O$ at 105°, and of $6H_2O$ at 205° is more readily explained by the former, but the chromium content and particularly the possibility of the preparation of anhydrous chromium chromate from the substance, favour the formula $Cr_2O_3.CrO_3.7H_2O$. The analytical data agree equally well with those required for the peroxide, CrO_2, but the readiness with which the substance is converted by ammonia, alkali carbonate, or hydroxide or by boiling water into chromium hydroxide and chromate is interpreted in favour of a salt-like constitution. W. Manchot and R. Kraus said that the product obtained by heating chromic hydroxide to 320° to 345° for several hrs. is a hygroscopic, black powder containing 6 to 7 per cent. of water. Its general properties are those of a peroxide and not of a chromic chromate, and the formula is probably $O : Cr : O$. It thus differs from the peroxide, $O : Cr.O.O.Cr : O$, which appears as the primary product of the autoxidation of chromous oxide. The existence of this chromium dioxide is regarded as evidence in favour of the view that chromium is quadrivalent in chromium trioxide. A. Simon and T. Schmidt observed that oxygen is given off, and the dioxide passes into chromic oxide at 380°. E. Moles and F. Gonzalez gave for the magnetic susceptibility $42{\cdot}2\times10^{-6}$ units.

Chromium dioxide is a dark grey, almost black, solid which gives off oxygen at 300° forming green chromic oxide. L. and P. Wöhler said that the decomposition of chromium dioxide in vacuo begins at about 280°. When prepared by igniting hydrated chromic oxide, W. Manchot and R. Kraus found that it contained 6 or 7 per cent. of water which is evolved along with oxygen at a red-heat, and chromic oxide remains. E. Hintz found that when heated with **chlorine,** at about 250°, it forms chromic and chromyl chlorides; when treated with **water,** it forms no chromic acid; but M. Martinon found that with **hydrogen dioxide,** oxygen is rapidly evolved at 68°, and the addition of a few drops of sulphuric acid results in the formation of blue perchromic acid. This agrees with the hypothesis that the dioxide is chromium chromate. H. Moissan, and W. Manchot and R. Kraus found that it reacts slowly with **hydrochloric acid** liberating chlorine; and it likewise reacts with **hydriodic acid** liberating iodine. M. Krüger said that with a mixture of pyrosulphuric acid and **sodium chloride,** chlorine and not chromyl chloride is formed; and with conc. sulphuric acid and sodium chloride, C. W. Eliot and F. H. Storer obtained chromyl chloride. H. Moissan, O. Popp, etc., found that it is soluble in **sulphuric acid.** W. Manchot and R. Kraus found that when warmed with **sulphur dioxide,** sulphur trioxide is formed; and warm **sulphurous acid** is converted into sulphuric acid. C. W. Eliot and F. H. Storer, O. Popp, etc., observed that chromic dioxide readily dissolves in dil. **nitric acid;** the soln. is reddish-brown, and gives a dirty green precipitate with ammonia. W. Manchot and R. Kraus found that conc. nitric acid converts the dioxide into chromic acid. E. Hintz found that it is scarcely attacked by **phosphorus pentachloride** at 250°. A. Maus stated that a little **arsenic acid** converts the dioxide into chromic arsenate, which is soluble in an excess of arsenic acid. The dioxide is insoluble in **ether, acetone,** and other organic liquids; and O. Popp said that the dioxide dissolves with difficulty in **acetic acid.** M. Krüger, W. Manchot and R. Kraus, etc., observed that boiling **potassium** or **sodium hydroxide** converts the dioxide into a soln. of alkali chromate, and a precipitate of hydrated chromic oxide. This simultaneous oxidation and reduction furnishes an illustration of the acidic and basic properties of chromium dioxide. A. Maus found that when digested with **lead acetate** in the presence of acetic acid, lead chromate and chromic acetate are formed. E. Maumené said that the brown oxide is soluble in aq. **chromic acid,** or in soln. of **alkali dichromates,** and when the brown soln. are diluted with water, the brown oxide is re-precipitated.

I. Schukoff[4] heated chromic anhydride to 500°–510° and obtained *chromium tetritaenneaoxide*, Cr_4O_9, or $Cr_2O_3.2CrO_3$. The magnetic qualities of this substance disappear at 120°–130°, and reappear on cooling. For $Cr_2O_3.6CrO_3$, *vide infra*, chromium dichromate. For **chromium pentitatridecoxide,** Cr_5O_{13}, *vide supra*. The heating curve of A. Simon and T. Schmidt is shown in Fig. 22, and the dissociation press. in Fig. 23. According to J. W. Döbereiner, and M. Traube, **chromium pentitadodecoxide,** Cr_5O_{12}, or $Cr_2O_3.3CrO_3$, *i.e.* normal *chromium chromate*, or *chromic chromate*, $Cr_2(CrO_4)_3$, is formed when chromic anhydride is heated to about 250°. By boiling the product with water, or after standing a long time in contact with that liquid, it is converted into a soluble modification. The other reactions resemble those obtained with the preceding oxide. A. Simon and T. Schmidt's heating curve is shown in Fig. 22, and the dissociation press. curve in Fig. 23. G. Rothaug's observations were discussed in connection with the oxidation of chromic oxide. S. Takegami observed that chromic chromate is sometimes deposited in a colloidal form on the cathode during the electrolysis of soln. of chromic acid. This occurs when the ratio of ter- to sexivalent chromium is 1 : 0·5. Observations were previously made by E. Müller and co-workers who regard the film as $Cr_2(OH)_4CrO_4$—*vide supra*, the deposition of chromium. A. Maus found that *chromium hexitapentadecaoxide*, Cr_6O_{15}, or $Cr_2O_3.4CrO_3$, is formed when a hydrated chromic oxide or chromic carbonate is dissolved in a cold, aq. soln. of chromic acid, and the soln. evaporated. The brittle, horny product is permanent in air, and dissolves without change in alcohol; the soln. may be evaporated a number of times at 100° without decomposition, but A. A. Hayes observed that if kept for a long time at that temp. the compound becomes insoluble. K. Honda and co-workers obtained this product by heating chromium trioxide to 280°, and they said that its magnetic susceptibility at room temp. is $14{\cdot}2\times10^{-6}$. C. D. Braun treated a conc. aq. soln. of potassium ferrocyanide with potassium dichromate, and on evaporation obtained a resinous mass of the *dodecahydrate*, $Cr_6O_{15}.12H_2O$.

C. W. Eliot and F. H. Storer summed up the result of their examination of these intermediate oxides by saying: "There is not a particle of evidence of the existence of any chromate of chromium containing more than one equivalent of chromic acid." The position is very nearly the same to-day.

According to J. Heintze,[5] by passing a slow current of ammonia into a dil. chloroform soln. of chromyl chloride and by evaporating the solvent, there remains brown **ammonium chromochromate,** $NH_4O.CrO_2.O.Cr.O.CrO_2.ONH_4$, which loses water and ammonia when heated, forming chromic oxide. The salt forms a brownish-yellow soln. with water, but it is insoluble in alcohol, ether, chloroform, and glacial acetic acid; it dissolves in conc. acids, and the acid soln., when diluted with water, deposits the original salt as a brown powder. The salt is decomposed by soda-lye, giving off ammonia. J. Heintze prepared **potassium chromochromate** in an analogous manner, but neither A. Leist, nor A. Werner and A. Klein could verify this. D. Tommasi reported **potassium chromic hydroxychromate,** $K_2CrO_4.2Cr(OH)CrO_4$, to be formed by the action of nitric oxide on a soln. of one part of potassium dichromate in 2 parts of fuming nitric acid, at 70°; evaporating the product to dryness on a water-bath; extracting with hot water; and drying at 150°. The violet-brown, amorphous powder is without taste or smell; its sp. gr. at 14° is 2·28; it melts at 300°, and decomposes: $K_2CrO_4.2Cr(OH)CrO_4 = 2Cr_2O_3 + K_2CrO_4 + H_2O + 3O$. When mixed with potassium chlorate it does not detonate by percussion, but it burns vigorously when heated. It is insoluble in water, alcohol, and acetic acid; conc. nitric acid has very little action in the cold, but when heated the salt is partially oxidized. The salt is not attacked by cold, conc. sulphuric acid, but the hot acid forms a green soln.; and with hot, conc. hydrochloric acid, chlorine is evolved.

§ 13. Chromium Trioxide, and Chromic Acid

The oxidation of chromic oxide, or hydrated chromic oxide furnishes **chromium trioxide,** or **chromic anhydride,** CrO_3; it was discovered by A. Mussin-Puschkin,[1] and afterwards investigated by L. N. Vauquelin, H. Moser, and J. B. Richter. Chromic oxide is oxidized to chromium trioxide, as previously indicated, by heating it in the presence of bases in air. J. Milbauer found that with oxygen at 12 atm. press., and 300°, only a partial conversion of chromic oxide to chromium trioxide occurs; and the conversion is complete at 460° and 12 atm. press. in the presence of the oxides of silver, magnesium, zinc, cadmium, and lead. The oxidation occurs more readily than with oxygen if chromic oxide be heated with oxidizing agents—*e.g.* alkali nitrate, chlorate, dioxide, etc. A. Mailfert found that ozone converts chromic hydroxide into chromium trioxide. In alkaline soln., chromic oxide or hydroxide is oxidized to the trioxide by chlorine or hypochlorite (A. J. Balard,

H. Vohl), fluorine (F. Fichter and E. Brunner), bromine (F. H. Storer, F. Melde), iodine (E. Lenssen), hydrogen dioxide or alkali dioxide (E. Lenssen), potassium persulphate (H. Marshall, and D. M. Yost), potassium ferricyanide (E. Lenssen), potassium permanganate (A. Reynoso, S. Cloez and E. Guignet, and E. Bohlig), perchloric acid (J. J. Lichtin), lead dioxide (G. Chancel), manganese dioxide (F. H. Storer), mercuric oxide (F. H. Storer), copper oxide (O. W. Gibbs), and silver oxide (D. Meneghini). In acidic soln., according to F. H. Storer, A. Terni, and M. Salinger, chromic oxide is oxidized by potassium permanganate, or by lead or manganese dioxide; and, according to M. Holzmann, by ceric nitrate. O. Stumm found that chromic salts in alkaline soln. can be oxidized by molecular oxygen, using manganese hydroxide, copper hydroxide, cerium hydroxide, silver oxide and iodide, and amalgamated copper as catalytic agents. For the electrolytic oxidation, *vide supra*, the extraction of chromium.

K. Fischbeck and E. Einecke found that the cathodic polarization of ferrous, cuprous, calcium, and magnesium chromites produces chromic acid, whilst the other chromites are unaffected, and natural chrome ironstone behaves in a like manner, but other commercial chromites are reduced on cathodic polarization, and yield chromic acid on anodic polarization. Chromites behave as an intermediate electrode. O. Unverdorben observed that chromyl fluoride, prepared by heating a mixture of fluorspar, lead chromate, and sulphuric acid, when passed into water, furnishes an aq. soln. of this oxide. The soln. was treated with silver nitrate, and the washed precipitate of silver chromate decomposed by hydrochloric acid. A. Maus said that anhydrous sulphuric acid or fuming sulphuric acid is not suited for the preparation because of its volatilization with the chromyl fluoride. J. J. Berzelius employed a somewhat similar process using either lead or barium chromate. A. Maus treated a hot soln. of potassium dichromate with insufficient hydrofluosilicic acid to precipitate all the potassium; the filtered soln. was evaporated and again treated with hydrofluosilicic acid, and evaporated to dryness in a platinum dish. The residue was taken up with a little water, filtered, and evaporated for chromic anhydride. D. G. Fitzgerald and B. C. Molloy precipitated the potassium as potash-alum by adding aluminium sulphate, and removed the sulphuric acid by ignition. J. Fritzsche added a warm soln. of potassium dichromate to an excess of conc. sulphuric acid; the chromic anhydride separates in small red crystals. The liquid is drained from the crystals, which are then dried on a porous tile over sulphuric acid. The crystals are then recrystallized from an aq. soln. P. A. Bolley said that the chromic anhydride so prepared contains a little sulphuric acid as impurity and the Metals Protection Corporation removed the sulphate by means of barium hydroxide, carbonate, or chromate. R. Bunsen, A. V. Rakowsky, A. Dalzell, F. Dietze, O. Ficinus, H. Moissan, A. Schafarik, M. Traube, J. Voisin, G. Vulpius, R. Warington, and E. Zettnow employed modifications of these processes.

G. P. Baxter and co-workers purified chromium trioxide suitable for at. wt. determinations by repeated filtration, and recrystallization from aq. soln. M. Siewert treated barium chromate with nitric acid, crystallized out the barium nitrate; removed the nitric acid by evaporation to dryness; and recrystallized the product. E. Duvillier used a similar process, and afterwards substituted lead chromate for barium chromate. K. F. W. Meissner, F. Kuhlmann, J. W. Döbereiner, and W. A. Rowell treated barium chromate with sulphuric acid; and A. Schrötter, lead chromate. The filtered liquid in each case was evaporated for crystallization. J. Thomsen, and J. Krutwig similarly treated silver chromate with hydrochloric acid. A. Mailfert found that chromium trioxide is formed when soln. of chromic salts or chromic oxide are treated with ozone. M. Prud'homme and F. Binder observed that if barium chloride is added to a soln. of barium dichromate, normal barium chromate is precipitated, and potassium chloride and chromic acid remain in soln. In preparing chromic acid, V. V. Polyansky first obtained calcium chromate by addition of calcium hydroxide paste, followed by calcium chloride soln., to aqueous sodium dichromate ; the mixture is concentrated on the water-bath, the precipitate of calcium chromate being collected and dried. Two parts of the aq. soln. is treated with one part of sulphuric acid (sp. gr. 1·84), kept on the water-bath, decanted, and this procedure repeated until no more calcium sulphate is precipitated, when chromic anhydride is crystallized. The product is treated with nitric acid (sp. gr. 1·4), and dried at 60°–100°.

For the electrolytic oxidation of soln. of chromic salts to chromic acid or the chromates, *vide supra.* According to E. Müller and M. Soller, a soln. of chrome-alum in N-H_2SO_4 is not appreciably oxidized to chromic acid with a smooth platinum anode, but when traces of a lead salt are present in the soln., lead dioxide is deposited on the anode, and oxidation then occurs. About one-third of the oxidation which occurs with a lead dioxide anode occurs when an anode of platinized platinum is used. With a lead dioxide anode, the oxidation occurs quantitatively in fairly conc. soln. of chrome-alum, when the current density is not too high—about 0·005 amp. per sq. cm. is suitable. The difference in the results is not due to the lead dioxide anode having a higher potential than the platinum anode, since the reverse is rather the case. The effect is attributed to the catalytic action of lead dioxide which oxidizes the chrome-alum chemically. P. Askenasy and A. Révai showed that in regenerating soln. of chromic sulphate, at first, when the conc. of the chromic acid is small, it is better to use low-current densities at the cathode, and to increase the current density as the conc. of chromic acid increases. Temp. has little influence on the process. The addition of magnesium sulphate prevents a reduction at the cathode when dil. soln. and low current densities are employed, but if there is only a small percentage of chromic acid present it has the opposite effect, and if high current densities are used, it has no effect. The influence of chromium sulphate is to prevent reduction with both high and low-current densities except in soln. which contain very little chromic acid. The addition of sodium and potassium sulphates is without influence on the reaction. Dilution is favourable to the oxidation under all circumstances, but more especially with high-current densities and in the presence of magnesium sulphate when low-current densities are employed. A high conc. of sulphuric acid has a slightly favourable action. A. R. y Miro found that the presence of potassium fluoride favours the electrolytic oxidation of chrome-alum to potassium dichromate.

It is doubtful if hydrated chromium trioxide has been prepared in the solid state. H. Moissan[2] said that if an almost sat. aq. soln. of chromium trioxide be kept for several hrs. at about 90°, and then cooled below 0°, small red crystals of **chromic acid,** H_2CrO_4, collect on the walls of the containing vessel. This does not agree with J. J. Berzelius's observations, while F. Mylius and R. Funk, T. Costa, and E. Field were unable to confirm H. Moissan's observation. H. C. Jones showed that the f.p. of aq. soln. of chromium trioxide agreed with the assumption that the solvation for soln. with m mols of CrO_3 per litre, can be represented by the mols of water in combination with a mol of CrO_3 :

Mols CrO_3 per litre .	0·10	0·50	1·00	2·00	3·00	4·00
Mols H_2O per mol CrO_3 .	27·8	20·6	19·17	13·95	11·65	10·41

The crystals are chromium trioxide, CrO_3, not chromic acid, H_2CrO_4. The **solubility** of chromium trioxide in water was measured by R. Kremann who found that sat. soln. at $\theta°$ contained S grms. of CrO_3 per 100 grms. of soln.

	−74·0°	−64·0°	−52·0°	−43·0°	−28·3°	−16·3°	−2·0°
S	55·00	54·00	52·00	49·10	40·80	30·20	8·00

There is a eutectic at —105° with 57·2 per cent. of CrO_3. E. H. Büchner and A. Prins gave —155·0° for the eutectic with 60·5 per cent. of CrO_3. At higher temp. J. Koppel and R. Blumenthal, F. Mylius and R. Funk, and R. Kremann found :

	0°	15°	30°	50°	82°	100·0°	127·0°
S	61·82	62·40	62·52	64·60	66·00	67·40	71·20

The results of E. H. Büchner and A. Prins are plotted in Fig. 24 ; there is no sign of the formation of a definite hydrate. C. F. Hüttig and B. Kurre also failed to find any evidence of the formation of any definite hydrate. Analyses of chromium trioxide by L. N. Vauquelin, S. M. Godon de St. Menin, C. F. Rammelsberg, J. J. Berzelius, and A. Schrötter are in agreement with the empirical formula CrO_3. W. Ostwald's observations on the electrical conductivity, and the lowering of the f.p. indicate that the **molecular weight** in aq. soln. of chromium trioxide corresponds with **dichromic acid,** $H_2Cr_2O_7$; and this is in agreement with a comparison of the absorption spectra of aq. soln. of chromium trioxide and potassium dichromate, for H. Settegast found these spectra are very much alike. According to R. Abegg and A. J. Cox, the electrical conductivity and f.p. of soln. of the dichromates agree with the assumption that dichromic acid, $H_2Cr_2O_7$, chromic acid, H_2CrO_4, and chromium trioxide are present. E. Spitalsky, however, interpreted the results of his observations on the ionization of the aq. soln. to mean that the soln. is ionized $H_2Cr_2O_7 \rightleftharpoons 2H^{\cdot} + Cr_2O_7{}''$. The resolution of the dichromate into chromate ions was not observed with a mol of CrO_3 in 5800 litres. E. Field's observations on the raising of the b.p. of aq. soln. indicate a mol. wt. of 171·85 when H_2CrO_4 requires 118·4, and $H_2Cr_2O_7$ requires 218·8. T. Costa's ebulliscopic measurements show that soln. which are not too concentrated, at 100° contain $H_2Cr_2O_7$, not H_2CrO_4 ; and that a soln. of chromic acid has the same electrical conductivity when cooled to 0° either directly or after heating to 100°, so that no chromic acid, H_2CrO_4, is formed in soln. K. Seubert and J. Carstens explained the action of hydrazine on the assumption that the soln. contained $H_2Cr_2O_7$, or $Cr_2O_7{}''$-ions. M. S. Sherrill found that the f.p. of soln. of ammonium chromate agreed with the assumption that $HCrO_4{}'$-ions are present. W. V. Bhagwat and N. R. Dhar, N. R. Dhar, and F. Auerbach assumed the existence of H_2CrO_4 in aq. soln. H. Lessheim and co-workers, and P. Niggli discussed the electronic structure.

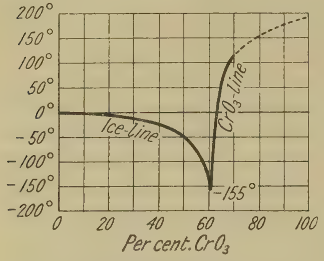

FIG. 24.—Solubility Curve of Chromium Trioxide.

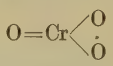
The generally accepted view—*vide supra*—is that chromium is sexivalent in the trioxide ; but W. Manchot supposed that it is quadrivalent :

Sexivalent Cr



Quadrivalent Cr

he supported this hypothesis by comparing the reactions of the trioxide with those of the peroxides, but R. Luther and T. F. Rutter did not agree. A. Geuther supposed that the polychromates are salts of hypothetical polychromic acids :

Dichromic acid.

Trichromic acid.

Tetrachromic acid.

A. Miolati represented chromic acid on the co-ordination theory by $H_2[CrO_4]$, and the polychromic acids by $H_2[Cr(CrO_4)O_3]$, in which the oxygen atoms of the O_3-group are replaced by CrO_4-radicles :

$$H_2\left[Cr^{(CrO_4)}_{O_3}\right]$$

Dichromate, $-H_2Cr_2O_7$.

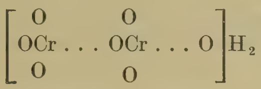
$$H_2\left[Cr^{(CrO_4)_2}_{O_2}\right]$$

Trichromate, $-H_2Cr_3O_{10}$.

$$H_2\left[Cr^{(CrO_4)_3}_{O}\right]$$

Tetrachromate, $-H_2Cr_4O_{13}$.

In addition to a number of inorganic polychromates, R. Weinland and H. Staelin prepared dichromates of quinoline and guanidine ; and trichromates of quinoline, pyridine and guanidine. A. Werner represented dichromic acid as a derivative of dimolecular chromium trioxide $(CrO_3)_2$, and on his co-ordination theory, dichromic acid becomes:



$$\left[\begin{matrix} O & & O & & \\ OCr & \ldots & OCr & \ldots & O \\ O & & O & & \end{matrix}\right]H_2$$

The physical properties of chromium trioxide.—The evaporation of the aq. soln. of chromium trioxide furnishes a dark red mass. The colour was found by F. Rinne [3] to darken with a rise of temp., and to be restored on cooling. When the trioxide is crystallized in the presence of sulphuric acid, dark red, needle-like **crystals** are formed, which, according to A. E. Nordenskjöld, are rhombic bipyramids with the axial ratios $a:b:c=0·692:1:0·628$. The fused trioxide furnishes a hard, brittle, coral-red, crystalline mass, which forms a scarlet-red powder. L. Playfair and J. P. Joule gave 2·676 for the **specific gravity** of the crystallized trioxide; C. H. D. Bödeker gave 2·737 at 14°, and for that which had been fused, 2·629 at 14°, while A. Schafarik gave 2·819 at 20°; W. A. Roth and G. Becker, 2·80 at 21°; and E. Zettnow, 2·775 to 2·804. H. C. Jones and H. P. Bassett measured the sp. gr. of soln. with from 0·10 to 4·00 mols of CrO_3 per litre with the idea of calculating the solvation of chromium trioxide in soln.—*vide supra.* The sp. gr. of aq. soln. of the trioxide were determined by D. J. Mendeléeff, and E. Zettnow; the following are averages of the two sets of observations, at 15°:

CrO_3 .	5	10	15	20	30	40	50	60 per cent.
Sp. gr. .	1·0365	1·0760	1·1185	1·1640	1·2630	1·3780	1·5110	1·656

H. R. Moore and W. Blum found the sp. gr. at 25° of soln. of chromic acid containing at 25°, C mols of CrO_3 per litre:

C . .	1	2	3	4	5	6	7	8	9	10
Sp. gr. .	1·0125	1·1383	1·2041	1·2699	1·3358	1·4016	1·4674	1·5332	1·5990	1·6648

W. Biltz discussed the mol. vol.; and C. del Fresno, the contraction in vol. which occurs when the compound is formed. The **viscosity,** η (water unity) dynes per cm. for aq. soln. of chromium trioxide containing ω grm. CrO_3 per 100 grms. of water, is:

0°	ω . . .	111·4	72·86	51·38	29·59
	η . . .	1·482	1·195	1·110	1·057
18°	ω . . .	98·8	71·01	35·92	16·71
	η . . .	1·5116	1·2849	1·1017	1·0349
25°	ω . . .	147·4	89·40	42·68	12·05
	η . . .	2·3360	1·4880	1·1360	1·024
40°	ω . . .	111·4	72·86	51·38	16·55
	η . . .	1·328	1·164	1·1055	1·027

S. A. Mumford and L. F. Gilbert found the sp. gr. of soln. of chromic acid containing M mols per litre at 25°/4°, to be:

M . . .	10·713	7·288	5·176	2·322	0·842	0·206	0·060	0·013
Sp. gr. . .	1·7042	1·4835	1·3479	1·1530	1·0602	1·0119	1·0012	0·9981

and at 45°/4°:

M . .	10·768	7·034	5·890	2·829	2·069	1·082	0·459	0·226
Sp. gr. . .	1·6954	1·4593	1·3813	1·1831	1·1306	1·0599	1·0226	1·0063

G. G. and I. N. Longinescu calculated the sp. gr. of the soln. considered as a binary mixture. C. del Fresno, and D. Balareff studied the mol. vol. R. Dubrisay measured the **surface tension** during the progressive neutralization of chromic acid soln. by soln. of sodium hydroxide, and by ammonia, and found that chromic acid differs from a strong dibasic acid, such as sulphuric acid, in exhibiting a constant surface tension only until the first acid function is neutralized, after which the surface tension decreases gradually but slightly until the second is neutralized, when, as usual, a great decrease occurs. T. Graham made observations on the rate of **diffusion** of chromium trioxide in aq. soln.

The **specific heat** of aq. soln. of chromium trioxide, between 21° and 53°, was measured by J. C. G. de Marignac.[4] E. H. Buchner and A. Prins gave for soln. with the molar ratio $CrO_3 : nH_2O$:

n	3·55	5·02	9·91	25·2	50	87·9	100·5	200
Sp. ht.	0·506	0·557	0·665	0·803	0·876	0·927	0·942	0·970

The last two sets of data are by J. C. G. de Marignac. The subject was discussed by N. de Kolossowsky. O. Unverdorben, J. J. Berzelius, H. Moissan, E. Hintz, and A. Schafarik observed that when chromium trioxide is heated, it becomes almost black and then melts to a reddish-brown liquid. M. Traube gave 180°–190° for the **melting point ;** F. M. Jäger and H. C. Germs, 198° ; and E. Groschuff said that the trioxide melts at 196° with a little decomposition, and that the molten mass can be easily under-cooled 26° ; E. Zettnow gave 170°–172° for the f.p., and said that on solidification, the temp. may rise to 193° ; and that there is a large contraction on solidification. The **freezing points** of aq. soln. of chromium trioxide are indicated in Fig. 24. J. Koppel and R. Blumenthal gave :

CrO_3	23·1	28·6	44·4	50·0	54·5 per cent.
Freezing point	−6°	−9·3°	−24°	−36°	−51°

and W. Ostwald, and R. Abegg and A. J. Cox made observations on the mol. lowering of the f.p. of aq. soln. H. C. Jones and H. P. Bassett found that with soln. containing m mol of CrO_3 per litre, the lowering of the f.p. was :

m	0·10	1·0	2·5	4·00
Fall of f.p.	5·26°	6·78°	9·00°	14·40°

E. Cornec measured the lowering of the f.p. of aq. soln. of chromic acid during its progressive neutralization with sodium hydroxide. There is a break in the curve corresponding with the formation of the dichromate, and another break corresponding with the chromate. J. J. Berzelius, A. Schafarik, H. Moissan, and E. Hintz noticed that when heated to near the b.p. of sulphuric acid, chromium trioxide **volatilizes** forming reddish fumes. O. Unverdorben, A. Schafarik, and J. J. Berzelius observed that chromium trioxide decomposes above its m.p. into oxygen and chromic oxide with a glow, but if the chromium trioxide has been obtained by evaporation no glowing occurs. H. Arctowsky said that decomposition occurs at 200° ; and I. Schukoff added that the trioxide decomposes with deflagration at 300°, with the evolution of oxygen. L. and P. Wöhler said that below 1200°, the reaction $2CrO_3 = Cr_2O_3 + 3O$ is not reversible and is probably exothermal ; but in the presence of potassium sulphate, at 1000°, the reaction, $2K_2SO_4 + Cr_2O_3 + 3O \rightleftharpoons 2(K_2SO_4.CrO_3)$, is reversible, and at 1009°, the press. of the oxygen is 878 mm. ; at 1029°, 785 mm. A. Simon and T. Schmidt's heating curve, and dissociation press. curve are shown in Fig. 22. K. S. Nargund and H. E. Watson found that 2 hrs.' heating at 300° resulted in a 28 per cent. decomposition ; at 350°, 48 per cent. ; at 400°, 52 per cent. ; at 550°, 100 per cent. ; 9 hrs. at 350°, 52 per cent., and 18 hrs. at 350°, 55 per cent. R. Read observed that in the non-luminous flame chromium trioxide decomposes with a bright, white incandescence. H. Arctowsky noticed that when heated to 125°, under 16 mm. press., chromium trioxide volatilizes forming a sublimate of long, red needles. J. Koppel and R. Blumenthal observed the **boiling points** of aq. soln. of chromium trioxide, at ordinary press. :

CrO_3	10·81	24·08	45·15	61·54	71·24 per cent.
Boiling point	102°	102°	110·5°	120°	127°

and T. Costa found the mol. rise of the b.p. of aq. soln. to be :

CrO_3	1·5233	1·7886	3·8212	11·5159 per cent.
Rise of temp.	15·6°	14·3°	14·1°	13·7°

Observations were also made by E. Field—*vide supra.* W. G. Mixter gave for the **heat of formation** of chromium trioxide, CrO_3, from its elements, 140 Cals.; amorphous chromic oxide, 36·2 Cals.; and from crystalline chromic oxide 26·1 Cals., whilst M. Berthelot gave 26·2 Cals. W. A. Roth and G. Becker gave $(Cr,\frac{3}{2}O_2)=147{\cdot}1$ Cals.; and for the heat of reduction of CrO_3 to Cr_2O_3, $-6{\cdot}1$ Cals. J. Thomsen gave for the heat of formation in aq. soln., 18·913 Cals., and M. Berthelot, 10·6 Cals. The subject was discussed by A. Berkenheim. According to F. Morges, the heat of solution of CrO_3 in water is $CrO_3+H_2O=H_2CrO_4+580$ cals.; for $H_2CrO_4+H_2O$, 340 cals.; for $H_2CrO_4.H_2O+H_2O=260$ cals.; for $H_2CrO_4.2H_2O+H_2O$, 135 cals.; $H_2CrO_4.3H_2O+H_2O$, 171 cals.; $H_2CrO_4.4H_2O+H_2O$, 80 cals.; $H_2CrO_4.5H_2O+H_2O$, 35 cals.; $H_2CrO_4.5H_2O+25H_2O$, 500 cals.; and $H_2CrO_4.30H_2O+25H_2O$, 210 cals. P. Sabatier gave 1·9 cals. for the heat of soln. in 40 times its weight of water at 19°. E. H. Büchner and A. Prins gave for the **heat of dilution** from $CrO_3.nH_2O$ to $CrO_3.80H_2O$, and the total heat of soln. when the heat of soln. for a mol of solid CrO_3 and 80 mols of water is 24·67 cals.:

n	3·32	4·03	4·96	10·1	25·2	49·9
Heat dilution	1447	1111	866	469	122	16
Heat solution	1020	1356	1601	1998	2345	2451

J. Thomsen gave for the **heat of neutralization,** $(CrO_3,NaOH_{aq.})=13{\cdot}134$ Cals.; for $(CrO_3,2NaOH_{aq.})=24{\cdot}720$ Cals.; P. Sabatier gave $(2CrO_3,K_2O_{aq.})=27{\cdot}0$ Cals.; $(2CrO_3,2K_2O_{aq.})=50{\cdot}8$ Cals.; while M. Berthelot gave $(2CrO_3,K_2O_{aq.})=26{\cdot}8$ Cals.; $(2CrO_3,2NH_{3aq.})=24{\cdot}0$ Cals.; for solid chromium trioxide, $(CrO_3,K_2O)=95{\cdot}6$ Cals.; $(2CrO_3.K_2O)=106{\cdot}8$ Cals., when for solids $(SO_3,K_2O)=141{\cdot}4$ Cals., and $(2SO_3,K_2O)=167{\cdot}6$ Cals.

E. Cornec measured the **index of refraction** of a soln. of chromic acid during its progressive neutralization with potassium hydroxide and with aq. ammonia. The results show that the aq. soln. of the acid first furnishes dichromate, and as the proportion of base increases, chromate is formed. W. J. Pope[5] gave 37·13 for the refraction equivalent of the CrO_4-radicle. J. Piccard and E. Thomas discussed the colour of chromate and dichromate ions. The **absorption spectrum** of aq. soln. of chromium trioxide was examined by J. H. Gladstone.[6] J. M. Hiebendaal showed that the green and blue rays are absorbed by the soln. According to A. Étard, there is a fine absorption band between $\lambda=6870$ and 6800 with conc. soln.; but soln. of potassium chromate and dichromate do not show this band. H. Settegast measured the absorption spectrum; and P. Sabatier found that the coeff. of absorption, a, for light of different wave-lengths, λ, is not sensibly affected by the thickness, λ, of the layer of liquid through which the light is passed. Here, $l=l_0 10^{-a\lambda}$ with light of intensity l_0:

λ	5450	5480	5550	5620	5690	5770	5850	5930
a	0·005	0·025	0·143	0·351	0·628	0·812	0·900	0·950

Beyond wave-length 5450 the coeff. becomes practically zero; in very dil. soln., the coeff. for wave-length 5180 is about 0·000013. The values are the same for the acid as for the salts, for solid potassium dichromate as for its soln., for the ammonium salt as for the potassium salt, and it follows that the absorption exerted by solid or dissolved alkaline dichromates is sensibly identical with that of the chromic acid which they contain. With soln. of potassium chromate, the absorption is in the blue and the violet, and with dilution, the absorption extends more in the direction of the red. Thus, O. Knoblauch found that in conc. soln., the absorption begins at 4900, and in dil. soln., at 5100. W. Böhlendorff obtained similar results; while J. M. Hiebendaal observed that the absorption begins at 5050, and in dil. soln. at 4770. K. Vierordt, P. Pogany, F. Grünbaum, A. Hantzsch, P. Bovis, N. R. Tawde and G. R. Paranjpe, G. Jander and T. Aden, M. N. Saha, C. P. Snow and F. I. G. Rawlins, and H. Settegast made observations on this subject; and P. Sabatier found that with potassium chromate soln., the coeff. of transmission, a, for soln. with one eq. of salt per litre, and, α_2, for soln. with 2 eq. per litre, were:

λ .	4940	4990	5030	5060	5080	5110	5130	5180	5240
α_1 .	—	0·06	0·18	0·325	0·44	0·61	0·69	0·85	0·92
α_2 .	0·025	0·108	0·207	0·43	0·51	0·62	0·69	0·84	0·93

The absorption is slightly greater in the more dil. soln., and this points to slight dissociation with formation of some dichromate, which, however, is only produced in very minute quantity. H. Becquerel found that soln. of potassim chromate are transparent for the ultra-red rays; and G. Massol and A. Faucon studied the transmission of ultra-violet rays. D. Brewster investigated the absorption spectrum of soln. of ammonium chromate; and J. H. Gladstone, soln. of metal chromates. H. von Halban and H. Siedentopf found that a soln. of potassium chromate in $0·05N$-KOH had the extinction coeff., ϵ, for light of wave-length, λ, when $I=I_0 10^{-\epsilon Cd}$, where C denotes the conc. in mols per litre.

λ .	2540	2650	2970	3130	3340	2800	2890	3600	4360
$\epsilon \times 10^{-3}$	2·35	3·00	0·927	0·1935	0·9850	3·290	2·086	4·416	0·3138

H. C. Jones and W. W. Strong found that the absorption spectra of conc. soln. of potassium chromate shows a stronger absorption than the value calculated from Beer's law. G. Rudorf discussed the applicability of Beer's law. F. Weigert, and H. von Halban and H. Siedentopf studied the absorption of light by mixed soln. of potassium chromate and copper sulphate. Observations on the absorption spectrum of soln. of potassium dichromate were made by H. Bremer, P. Glan, F. Grünbaum, H. C. Jones and W. W. Strong, B. K. Mukerji and co-workers, F. Melde, J. Müller, P. Pogány, P. Sabatier, H. Settegast, C. P. Smyth, G. Jander and T. Aden, and K. Vierordt. According to J. Formanek, aq. soln. of potassium dichromate absorb the blue and violet rays, and with decreasing concentration, the absorption extends in the direction of the red rays. O. Knoblauch found that with conc. soln., the absorption begins at 5200, and is complete at 4940, while with dil. soln., absorption begins at 5070, and is complete at 4840. W. Böhlendorff gave for the limit 5000, and J. M. Hiebendaal, 5250. A. Hantzsch's observations are summarized in Fig. 25. G. Hantzsch and R. H. Clark found that soln. of chromium trioxide in water and in aq. sulphuric acid are at all conc. optically identical with each other and with feebly acidic soln. of potassium dichromate. Soln. of the latter in water deviate very slightly in the direction of monochromate soln. Soln. of monochromates in water, in alkalis, and in methyl alcohol, are at all conc. quite different from dichromate and chromic acid soln. in their optical characteristics, but are identical among themselves, except for a slight deviation of the aq. soln. in the direction of the dichromate soln. The optical characteristics are independent, not only of the conc. and the solvent, but also of the temp. The chromophoric group in all acidic soln. is the completely saturated complex Cr_2O_7; in all alkaline soln. the corresponding complex is CrO_4. From the optical point of view, it is immaterial whether these complexes are combined with hydrogen or alkali metal, ionized or non-ionized; the colour of the ions must be the same as that of the non-ionized molecule. A. Hantzsch and C. S. Garrett explain the slight divergence from Beer's law with very conc., alkaline soln. of chromates by incomplete hydration rather than by ionization changes. All variations from the colorimetric law are attributed either to experimental errors, or to chemical changes between solvent and solute. H. M. Vernon estimated the degree of ionization from the colour

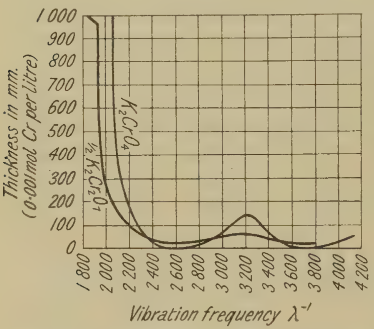


Fig. 25.—Absorption Spectra of Chromate Solutions.

of aq.soln. of the trioxide. E. Viterbi and G. Krausz measured the absorption spectra of soln. of chromic acid, and of potassium chromate and dichromate. There are seven feeble lines in the ultra-violet spectra of chromic acid and potassium dichromate which do not occur with soln. of the chromate. The bands with the chromate soln. are sharper than those with chromic acid or the dichromate. Except for a few minor differences, the spectra of the dichromate and of chromic acid are similar, and conform to Beer's law. Hence it is assumed that in these soln., the chromium is nearly all present as Cr_2O_7'', which has the same absorption spectrum either as an ion or as a non-ionized molecule; but probably with dil. soln. of the dichromate, there is some dissociation either as $Cr_2O_7''+H_2O\rightleftharpoons 2CrO_4''+2H^{\cdot}$, or as $Cr_2O_7''+H_2O \rightleftharpoons 2HCrO_4'$. Soln. of potassium chromate do not follow Beer's law, but the results with dil. soln. approach those with soln. of the dichromate, owing, probably, to a reaction $2CrO_4''+H_2O\rightleftharpoons Cr_2O_7''+2OH'$; and the addition of a large proportion of alkali displaces the equilibrium towards the left and restores the results for the absorption spectrum of the chromate. R. Robl observed but a faint luminescence in ultra-violet light; and A. Karl found the crystals triboluminescent. W. Spring found that there is a slight change of colour when soln. of potassium dichromate are allowed to stand. This shows that there is a change in the constitution of the soln. A. M. Taylor examined the **ultra-red spectrum**; D. M. Yost, the K-absorption spectrum; and N. Nisi, the **Raman effect**.

Both H. Buff,[7] and L. Bleekrode said that molten chromium trioxide is a good conductor of electricity, but J. W. Hittorf showed that the trioxide is a conductor only when it is contaminated with impurities, particularly water; the purified trioxide is a non-conductor. The **electrical conductivity** of aq. soln. was measured by R. Lenz, W. Ostwald, R. Abegg and A. J. Cox, E. Spitalsky, H. C. Jones and H. P. Bassett, etc. P. Walden found that with soln. containing a mol of the salt in v litres of water at 25°, the mol. conductivities, μ, are:

v	16	32	64	128	256	512	1024
μ	347·1	354·7	358·9	361·3	360·8	358·4	353·7

H. C. Jones gave for the molar conductivity, μ, at 0°, and the percentage **degree of ionization,** α,

v	0·286	0·500	1·000	2·500	5·00	10·00	20·00	40·00
μ	108·4	206·8	312·4	388·9	420·0	436·0	440·0	452·0
α	20·7	39·3	59·7	74·3	80·3	83·4	84·1	86·4

The conductivity at infinite dilution is 523. The assumption that the ionization is represented by $H_2CrO_4=H^{\cdot}+HCrO_4'=2H^{\cdot}+CrO_4''$, does not explain the facts. The nature of the molecules formed in aq. soln. depends on the composition, concentration, and temp. of the soln. This has been the subject of many investigations and the results are usually expressed in the language of the ionic hypothesis. Whatever be the equilibrium condition, that state is quickly attained; and the result was shown by K. Beck and P. Stegmüller, T. Costa, M. S. Sherrill, and P. Walden to be independent of the mode of preparation of the soln. A. Hantzsch's optical measurements show that it is very improbable that chromium trioxide exists in aq. soln. as CrO_3, or in the ionic form CrO_4'' or $HCrO_4'$. He therefore assumed that in solid, and in aq. soln., the equilibrium condition: $nCrO_3+H_2O\rightleftharpoons(CrO_3)n.H_2O$, is almost wholly in favour of the polymerized product.

With the most concentrated soln. of chromium trioxide in water, it is probable that trichromic and tetrachromic acids are formed, but in more dilute soln., only monochromic and dichromic acids are involved; the former may be ionized: $H_2CrO_4\rightleftharpoons H^{\cdot}+HCrO_4'=2H^{\cdot}+CrO_4''$, and the latter: $H_2Cr_2O_7\rightleftharpoons H^{\cdot}+HCr_2O_7' \rightleftharpoons 2H^{\cdot}+Cr_2O_7''$. It was, therefore, inferred that chromic acid, H_2CrO_4, exists in soln., and that it behaves as a monobasic acid $H(HCrO_4)$, ionizing: $H_2CrO_4 =H^{\cdot}+HCrO_4'$. R. Abegg and A. J. Cox took a similar view, and added that even with soln. of the dichromates, there is a relatively small proportion of Cr_2O_7''-ions, and that as the temp. rises, the Cr_2O_7''-ions form CrO_4''-ions and chromic acid.

E. Carrière and P. Castel studied the ionic equilibrium $2CrO_4''+2H^{\cdot}\rightleftharpoons Cr_2O_7''+H_2O$ at 20° by the conversion of barium chromate into barium dichromate by the addition of a measured amount of hydrochloric acid, the end-point being reached when the soln. becomes clear. The hydrogen-ion conc. of the equilibrium mixture was calculated from the law of mass action applied to the ions concerned assuming complete ionization, and good agreement was found between the observed and calculated values for low conc. The conc. of acid required decreases with temp., and the equilibrium constant at 18° is 3×10^{-15}. P. Walden concluded from the small change in the electrical conductivity of the soln. between the dilutions $v=32$ and $v=1024$, that a strong monobasic acid is involved and that this is almost completely ionized with the dilution $v=32$. W. Ostwald, however, concluded that the acid exists in aq. soln., not as H_2CrO_4, but as $H_2Cr_2O_7$; and in support of this he showed that an aq. soln. which contains a mol of a compound per kilogram lowers the f.p. $-1·85°$. Acetic acid gives nearly the normal value $-1·92°$; nitric acid gives $-3·70°$, nearly twice the normal value, in agreement with the assumption that it is almost completely ionized into $H^{\cdot}$ and NO_3' ions; sulphuric acid gives $-2·00°$ in agreement with the assumption that it is ionized $H_2SO_4\rightleftharpoons 2H^{\cdot}+SO_4''$ to the extent of about 0·6; and chromic acid gives $-1·34°$ in agreement with the assumption that it is completely ionized $H_2Cr_2O_7\rightleftharpoons 2H^{\cdot}+Cr_2O_7''$, and this is in accord with the observations of P. Walden. According to W. C. D. Whetham, the eq. conductivity, λ, of soln. of potassium dichromate containing m eq. per litre is:

m	0·00001	0·0001	0·001	0·01	0·1	0·2
λ	81·3	76·3	71·4	70·4	64·3	61·5

The rise of the conductivity with dilution up to $m=0·0001$ is unusually small, and this is attributed to the hydrolysis of the Cr_2O_7''-ions to the slow-moving $HCrO_4'$-ions. The unusually large rise in the conductivity when the soln. is diluted from $m=0·0001$ to $m=0·00001$, is attributed to the ionization $HCrO_4'\rightleftharpoons H^{\cdot}+CrO_4''$ or possibly $HCr_2O_7'\rightleftharpoons H^{\cdot}+Cr_2O_7''$. H. R. Moore and W. Blum found the electrical conductivity κ mhos of soln. of C mols of chromic acid per litre at 25° to be:

C		1	2	3	4	5	6	7	8	9	10
κ	0°	0·219	0·342	0·418	0·440	0·435	0·420	0·387	0·345	0·289	0·225
	25°	0·315	0·513	0·616	0·657	0·662	0·641	0·600	0·545	0·477	0·402
	45°	0·389	0·632	0·763	0·818	0·831	0·817	0·769	0·708	0·625	0·528

The resulting curves show a maximum for about $4M$-soln. at 0°; for $4·8M$-soln. at 25°; and for $5·0M$-soln. at 45°. This shift is greater than can be explained by the change in sp. gr. or in vol. conc. caused by the difference in temp.; it must therefore involve a difference in the degree or type of dissociation of the chromic acid. R. N. J. Saal found the equilibrium constant of the reaction $Cr_2O_7''+H_2O\rightleftharpoons 2HCrO_4'$ to be 0·019. The decomposition of dichromate to chromate may occur (i) in the alkaline region: $Cr_2O_7''+OH'\rightarrow CrO_4''+HCrO_4'$; (ii) in the acidic and neutral region: $Cr_2O_7''+H_2O\rightarrow 2HCrO_4'$; and (iii) diluting the soln. with acid and water: $Cr_2O_7''+H^{\cdot}+H_2O(\rightleftharpoons HCr_2O_7'+H_2O)\rightarrow 2HCrO_4'+H^{\cdot}$. N. R. Dhar studied this subject. According to E. Spitalsky, the **hydrogen-ion concentration,** $[H^{\cdot}]$, in dil. soln. of chromic acid of [Cr], is:

[Cr]	0·002446	0·001218	0·000609	0·000602	0·000344	0·000172
$[H^{\cdot}]$	0·00249	0·00121	0·000606	0·000595	0·000342	0·000166

so that the ratio $[H^{\cdot}]:[Cr]$ is nearly unity in harmony with the assumption that with dil. soln. of chromic acid, the ionization is: $H_2CrO_4\rightleftharpoons H^{\cdot}+HCrO_4'$. The electrometric titration of chromic acid soln. was made by A. Miolati and E. Mascetti, N. H. Furman, R. N. J. Saal, Y. Kato and T. Murakami, W. S. Hughes, N. Westberg, and L. Margaillan. H. T. S. Britton obtained the results summarized in Fig. 26, by means of the hydrogen electrode; analogous results were obtained with the oxygen electrode. It follows that chromic acid ionizes as a normal dibasic acid. The reaction $H_2CrO_4 \rightleftharpoons H^{\cdot} + HCrO_4{}'$ is almost complete in dil. soln., whereas the reaction $HCrO_4{}' \rightleftharpoons H^{\cdot} + CrO_4{}''$ is extremely small. A. Miolati and E. Mascetti measured the conductivity of soln. of chromic acid during its progressive neutralization with sodium hydroxide; E. Cornec made analogous observations with respect to the f.p., and indices of refraction of soln. of chromic acid being neutralized with sodium, potassium, or ammonium hydroxide; by L. Margaillan, on the e.m.f. of hydrogenized platinum and the soln. against a mercury cathode; and by R. Dubrisay, on the surface tension of the soln. In general, the soln. first forms the dichromate, and as more base is added, the chromate appears. This agrees with the assumption that the aq. soln. contains dichromic acid; and the result was confirmed by the observations of A. K. Datta and N. R. Dhar with respect to the index of refraction, and mol. vol. in soln.; by T. Costa, with respect to the b.p. of the soln.; and by H. C. Jones and H. P. Bassett, with respect to the f.p. of the soln.

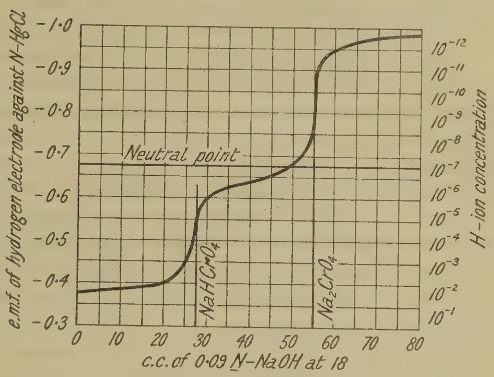

FIG. 26.—Electrometric Titration of Chromic Acid Solutions.

M. S. Sherrill attempted to reconcile the opposing hypothesis as to the nature of the ions in aq. soln. The depression of the f.p. of dil. soln. of chromic acid and potassium dichromate corresponds with their complete ionization into $Cr_2O_7{}''$-, and $H^{\cdot}$- or $K^{\cdot}$-ions, but the presence of some $HCrO_4{}'$-ions was assumed. The **ionization constant** for $2HCrO_4{}' \rightleftharpoons Cr_2O_7{}'' + 2H^{\cdot}$, was $K_1 = [Cr_2O_7{}'']/[HCrO_4{}']^2$, where $K_1 = 27$ with chromic acid soln., and 61 with soln. of potassium dichromate. From observations with ammonium chromate in dil. soln. in the presence of enough ammonia to prevent hydrolysis, $K_2 = [H^{\cdot}][CrO_4{}'']/[HCrO_4{}']$, where $K_2 = 5{\cdot}7 \times 10^{-7}$ at 18°; and from the partition of ammonia between aq. soln. of ammonium chromate, and chloroform, $K_2 = 6{\cdot}2 \times 10^{-7}$ at 18°, and $7{\cdot}4 \times 10^{-7}$ at 25°, so that the strength of chromic acid is about $\frac{1}{30}$th of that of acetic acid. H. T. S. Britton gave $4{\cdot}4 \times 10^{-7}$ for the second ionization constant at 18°; N. R. Dhar gave $K_2 = 5 \times 10^{-8}$; and W. S. Hughes, $K_2 = 10^{-7}$. W. V. Bhagwat and N. R. Dhar studied the subject. For H. Moissan's, and E. H. Riesenfeld and H. E. Wohler's observations on the electrolysis of soln. of chromic acid, *vide infra*, perchromic acid.

Attempts have been made to find the strength of chromic acid relatively with those of other acids. H. Settegast showed spectroscopically that chromic acid is displaced from chromates by sulphuric, formic, acetic, butyric, and tartaric acids. P. Sabatier showed colorimetrically that sulphuric, hydrochloric, phosphoric $H(H_2PO_4)$, and trichloracetic acids completely displace chromic acid from chromates. With acetic acid and the three equal acidic hydrogen atoms of citric acid, the action does not proceed quite so far. It is still less with the first acidic hydrogen of carbonic acid and the second acidic hydrogen of phosphoric acid, whilst the second acidic hydrogen of carbonic acid, boric acid, and the third acidic hydrogen of phosphoric acid have very little action at all. If the normal chromate is treated with an excess of solid boric acid, there is considerable formation of dichromate, owing to the production of an insoluble acid borate, the precipitation of which tends to make the action complete. From thermal data: $(K_2CrO_4,HCl) = 2{\cdot}4$ Cals.; and $(K_2Cr_2O_7,2HCl) = -0{\cdot}2$ Cal., M. Berthelot showed that hydrochloric acid should convert chromates into dichromates. He also found $(K_2CrO_4,6H_2SO_4) = 0{\cdot}76$ Cal.; $(K_2CrO_4,CH_3COOH) = 1{\cdot}5$ Cals.; and $(K_2CrO_4,CO_2) = -0{\cdot}4$ Cal.; and added that in soln. of neutral potassium chromate, strong acids cause the total, and weak acids the partial displacement of one of the two potassium-atoms, potassium dichromate being formed at the same time. This displacement is due not so much to the smaller heat of formation of the chromates compared with other acids capable of displacing chromic acid, as to the fact that the heat of formation of the dichromate is much greater than that of the neutral chromate, and that hence there is always a great tendency to the formation of the dichromate. This tendency renders the one potassium-atom in the neutral chromate easily replaceable—*vide infra,* the action of acids on potassium chromate. W. V. Bhagwat and N. R. Dhar favoured the view that chromic acid exists in soln. as H_2CrO_4, and potassium dichromate as $KHCrO_4$.

E. Spitalsky measured the catalytic effect of soln. of chromic acid on the decomposition of ethyl diazoacetate by G. Bredig's process. Dil. soln. of chromic acid contain almost exclusively the dibasic acid $H_2Cr_2O_7$, which in a dilution of 500 litres is dissociated almost completely into $H^{\cdot}$- and Cr_2O_7''-ions. Dil. soln. of potassium dichromate contain almost exclusively the ions of the normal salt, $K_2Cr_2O_7$. In accordance with this view, dil. soln. of potassium chromate, K_2CrO_4, behave like alkalies to chromic acid, inasmuch as the CrO_4''-ions are changed almost quantitatively into Cr_2O_7''-ions, and the soln. remains neutral. Conc. soln. of potassium dichromate are slightly acid, probably owing to slight hydrolysis according to the equation: $Cr_2O_7''+H_2O\rightleftharpoons 2CrO_4''+2H^{\cdot}$; the corresponding equilibrium constant $K_1=[CrO_4'']^2[H^{\cdot}]^2/[Cr_2O_7'']$ is $5{\cdot}1\times10^{-12}$. In a 0·1 molar soln. of the dichromate, the Cr_2O_7''-ions are hydrolyzed to the extent of 0·13 per cent. and in a 0·017 molar soln. to 0·28 per cent. so that the degree of hydrolysis does not alter much with dilution. Besides the hydrolysis, another reaction represented by the equation $CrO_4''+H^{\cdot}\rightleftharpoons HCrO_4'$ takes place to some extent in dichromate soln.; the corresponding constant $K_2=[CrO_4''][H^{\cdot}]/[HCrO_4']$ is $2{\cdot}7\times10^{-7}$. There is no evidence of the existence in dichromate soln. of complex ions such as Cr_3O_{10}''. J. Sand and K. Kästle showed that the acid resulting from the hydration of chromium trioxide is of medium strength, and suggested that in dichromate soln. there is the hydrolytic equilibrium: $Cr_2O_7''+H_2O\rightleftharpoons 2CrO_4''+2H^{\cdot}$, and in that case, from observations on a mixture of potassium iodate and iodide, the reaction $3Cr_2O_7''+5I'+IO_3'=6CrO_4''+3I_2$ is accelerated by $H^{\cdot}$-ions. The value of $K=[CrO_4'']^2[H^{\cdot}]^2/[Cr_2O_7'']$ calculated from these results is only approximately constant, and amounts to about $K=1{\cdot}5\times10^{-13}$ at 25°; and hence it follows that $0{\cdot}1N$-$K_2Cr_2O_7$ is hydrolyzed to the extent of about 0·18 per cent. The deviation from constancy is not due to the direct action of dichromate on potassium iodide, as the rate of reaction between these substances is much slower than the main reaction. The disturbance is probably due to the catalytic effect of some product formed during the reaction.

J. Lundberg studied the effect of chromate soln. on the hydrolysis of ethyl acetate. If the hydrolysis of potassium chromate proceeds: $CrO_4''+H_2O=HCrO_4'+OH'$, the equilibrium constant $K_1=[HCrO_4'][OH']/[CrO_4'']$; and if $2CrO_4''+H_2O=CrO_7''+2OH'$, then $K_2=[Cr_2O_7'']^{\frac{1}{2}}[OH']/[CrO_4'']$; both values were too irregular to decide which is correct, but conductivity measurements favour the former, and for $0{\cdot}1N$-K_2CrO_4, $K_1=1{\cdot}368\times10^{-7}$, and 0·012 per cent. of the salt is hydrolyzed; and in a $0{\cdot}1N$-$K_2Cr_2O_7$, containing chiefly $HCrO_4'$-ions, the salt is hydrolyzed to the extent of 0·094 per cent. in accord with $HCrO_4'=H^{\cdot}+CrO_4''$. Unlike E. Spitalsky, J. Lundberg assumes that a comparatively large proportion of $HCrO_4'$-ions is present in aq. soln. of potassium dichromate. For the observations of V. K. la Mer and C. L. Read, *vide infra,* sodium dichromate.

Observations on soln. of sparingly soluble chromates and dichromates have been made. Thus, R. Abegg and R. J. Cox studied the hydrolysis of mercuric chromate; M. S. Sherrill, silver chromate; and K. Beck and P. Stegmüller, lead chromate. From these results M. S. Sherrill calculated $[H^{\cdot}][CrO_4'']/[HCrO_4']=8{\cdot}4\times10^{-7}$ at 25° and $[HCrO_4']^2/[Cr_2O_7'']=0{\cdot}013$ at 25°; and K. Beck and P. Stegmüller, $[H^{\cdot}][CrO_4'']/[HCrO_4']=5{\cdot}7\times10^{-7}$ at 18°, and $[HCrO_4']^2/[Cr_2O_7']=2{\cdot}5$ at 18°.

Transport experiments on potassium chromate were made by J. F. Daniell and W. A. Miller, J. W. Hittorf, R. Lenz, O. Masson, B. D. Steele, R. B. Denison, and A. Charpentier; F. Kohlrausch calculated 72 for the **transport number** of $\frac{1}{2}CrO_4''$ from the conductivity data of calcium chromate; and M. S. Sherrill, 76·7 from the data of ammonium chromate; and 40 for the $HCrO_4'$-ion. W. Hittorf, E. H. Riesenfeld, and A. Charpentier made observations with potassium dichromate; and C. W. D. Whetham found the velocity of migration of the Cr_2O_7-ion to be 0·00047 cm. per sec. for a potential difference of one volt; and the transport number to be 91.

F. Morges found that the **electrolysis** of aq. soln. of chromium trioxide furnishes oxygen at the anode, and hydrogen and chromic chromate at the cathode. E. H. Riesenfeld found that in sulphuric acid soln. a perchromic acid is formed at the cathode. According to E. Liebreich, the thin layers of oxide or hydroxide on the cathode, which give rise to the periodic phenomena observed during the electrolysis of chromic acid are colloidal in nature; the oxide is drawn to the cathode just so long as a negative tension lies on it. The addition of chlorides brings about a displacement of two curves which make up the decomposition voltage curve of chromic acid. G. S. Forbes and P. A. Leighton studied the cathodic reduction of chromic acid to a chromic salt, and found the electrochemical yields with the cathode in light were about half per cent. greater than in darkness. Part or all this can be attributed to local heating in the thin diffusion layer above the cathode. The absence of any increase in the photochemical yield in light is compatible with light-sensitive chromate if the latter is equally reactive electrochemically before and after excitation. Granting that the slightly greater electrochemical efficiency in light is in part due to excited chromate, any estimate of the quantum yield requires several assumptions, especially one concerning the life of the excited individual upon which its chance of reaching the cathode depends. The subject was investigated by E. Müller and P. Ekwall, D. T. Ewing and co-workers, and A. Lottermoser and H. Walde. E. Liebreich showed that the thin layers of oxide or hydroxide, formed in the cathode during the electrolysis of soln. of chromic acid, are colloidal; they may give rise to colloidal phenomena; and the addition of chlorides displaces the two curves which make up the decomposition voltage of chromic acid. According to G. P. Vincent, the depolarizing action of a sat. soln. of potassium dichromate on hydrogen liberated at a smooth platinum electrode commences only when about 0·28 per cent. by vol. of conc. sulphuric acid is present. With a clean mercury cathode, the neutral soln. shows 100 per cent. depolarization of the hydrogen set free. The corrosion of zinc, iron, and copper by sat. soln. of potassium dichromate is produced only when the soln. is acidified. No corrosion occurs with sat. soln. of potassium dichromate when copper is short-circuited with mercury or platinum; or when iron is short-circuited with mercury. Zinc when short-circuited with mercury corrodes slightly, and more rapidly in 0·02 per cent. acetic acid soln. than in 0·02 per cent. sulphuric acid soln.

The data of L. Scherbakoff and O. Essin favour the view that in the electrolysis of conc. sulphuric acid soln. of chromic acid chromium is deposited by the discharge of chromic ions, but, according to E. Liebreich, with soln. in dil. acids, the data for current efficiencies favour the view that the metal is deposited by the discharge of chromous ions. S. Takegami studied the anodic oxidation of cathodically reduced chromic acid.

W. D. Bancroft measured the **oxidation potential** of potassium dichromate and chromic acid respectively at 16°–18°, and in $0·2M$-soln. with the following results: stannous chloride and potash-lye, 1·37, and 1·70 volt; stannous chloride and hydrochloric acid, 0·57, and 0·90 volt; sodium sulphide, 1·15, and 1·49 volt; hydroxylamine and potash-lye, 1·12, and — volt; hydroxylamine and hydrochloric acid, 0·43, and — volt; chromous acetate, 0·70, and 1·03 volt; chromous acetate and alkali-lye, 1·09, and — volt; pyrogallol and potash-lye, 0·98, and 1·32 volt; hydroquinone and potash-lye, 0·83, and 1·17 volt; sodium hyposulphite, 0·78, and 1·12 volt; sodium thiosulphate, 0·49, and 0·89 volt; sodium sulphite, 0·48, and 0·81 volt; sodium hydrosulphite, 0·40, and 0·73 volt; sulphurous acid, 0·35, and 0·68 volt; sodium hypophosphite, 0·55, and 0·88 volt; sodium phosphite, 0·47, and 0·80 volt; potassium arsenite, 0·56, and 0·89 volt; potassium ferrous oxalate, 0·78, and — volt. potassium ferrocyanide, 0·47, and 0·80 volt; potassium ferrocyanide and potash-lye, 0·59, and 0·93 volt; iodine and potash-lye, 0·57, and 0·91 volt; ferrous sulphate and sulphuric acid, 0·27, and 0·60 volt; ferrous sulphate, 0·43, and 0·76 volt; and cuprous chloride, 0·50, and 0·84 volt. B. Neumann measured the **potential** of the chromate electrode towards a normal electrode, and found for N-$K_2Cr_2O_7$, 0·79 volt; and for N-$H_2Cr_2O_7$, 1·11 volt. R. Ihle gave for sulphuric acid soln., —1·44 volt, and for alkaline soln., —0·46 volt; W. Hittorf, 1·2 volt; and F. Crotogino, 1·1 to 1·2 volt. The subject was investigated by K. F. Ochs. According to G. S. Forbes and E. P. Bartlett, certain reducing agents increase the oxidation potential of dichromate ions on platinum by amounts up to 0·2 volt—*e.g.* ferrous salts; and, according to L. Loimaranta, iodides. The phenomenon was discussed by R. Abegg, and R. Luther.

R. Luther emphasized the fact brought out by the observations of W. D. Bancroft, and B. Neumann, that the potential of chromic acid, and dichromates is augmented by increasing the acidity of the soln. Thus, if $[H^{\cdot}]$ denotes the conc. of the hydrogen ions, then, the oxidation potentials, E volt, referred to the hydrogen electrode, are:

$[H^{\cdot}]$.	1	0·1	0·01	0·001	0·0001	0·00001	0·000001
E .	1·29	1·05	0·91	0·86	0·81	0·75	0·66

The chromic oxide-chromic acid potential given by R. Abegg and co-workers for $Cr^{\cdot\cdot\cdot}+4H_2O+3\oplus\rightleftharpoons HCrO_4'+7H^{\cdot}$ is nearly 1·3 volt. In alkaline soln., the potential referred to the normal electrode for $Cr(OH)_{3solid}+5OH'+3\oplus\rightleftharpoons CrO_4''+4H_2O$, is —0·1 volt, and E. Müller gave 0·908 for the e.m.f. of the cell Pt | H_2, 0·01N-KOH | 0·01N-KOH, 0·025K_2CrO_4 | Pt. E. Spitalsky found the potential of a dichromate soln. to be about 0·85 volt in the presence of an $H^{\cdot}$-ion concentration of 10^{-3} to 10^{-4}. R. Luther observed that the oxidation of chromium, and bi- and ter-valent chromium to chromate ions yield an e.m.f. corresponding with 0·6 volt for $Cr_{metal}\rightarrow CrO_4''$ against a normal electrode; 1·1 volt for $Cr^{\cdot\cdot}\rightarrow CrO_4''$; and 1·5 volt for $Cr^{\cdot\cdot\cdot}\rightarrow CrO_4''$. In acidic soln., the CrO_4''-ion plays only a secondary part. In the case of $HCrO_4'$-ions, the e.m.f. are 0·4 volt for $Cr_{metal}+4H_2O+6\oplus\rightarrow HCrO_4'+7H^{\cdot}$; 0·9 volt for $Cr^{\cdot\cdot}+4H_2O+4\oplus\rightarrow HCrO_4'+7H^{\cdot}$; and 1·3 volt for $Cr^{\cdot\cdot\cdot}+4H_2O+3\oplus\rightarrow HCrO_4'+7H^{\cdot}$. These changes furnish $Cr_{metal}\rightarrow Cr^{\cdot\cdot}$, 0·3 volt; $Cr_{metal}\rightarrow Cr^{\cdot\cdot\cdot}$, 0·2 volt; $Cr^{\cdot\cdot}\rightarrow Cr^{\cdot\cdot\cdot}$, 0·1 volt. If an intermediate oxidation compound exists under the conditions of observation, this compound is a stronger oxidizing agent than the highest oxidation product, and a stronger reducing agent than the lowest oxidation product.

H. Moissan[8] said that aq. soln. of chromium trioxide are **photosensitive,** for they decompose with the evolution of oxygen, when exposed to light. M. Ponton found that although chromates are stable in light, they are rapidly reduced if organic substances be present—*e.g.* ammonium or potassium dichromate in contact with paper. J. M. Eder observed that glue, albumin, gum arabic, dextrine, cane-sugar, grape-sugar, glycerol, caseïn, alcohol, etc., act in this way. E. Kopp said that chromic oxide is formed. The reaction was observed by W. H. F. Talbot, A. Poitevin, and J. C. Schnauss. E. Goldberg said that the reaction between quinine and chromates is activated by light; but R. Luther and G. S. Forbes showed that the photoactivation of the chromate is negligibly small in comparison with that of the quinine. The subject was discussed by J. Plotnikoff, H. C. Winther, E. J. Bowen and C. W. Bunn, H. Zocher and K. Coper, B. K. Mukerji and N. R. Dhar, F. Weigert, G. S. Forbes and co-workers, M. Schiel, F. Schömmer, G. S. Forbes and P. A. Leighton, and R. E. Liesegang. J. Plotnikoff found that the chromate of ammonium, potassium or sodium suffers no decomposition when exposed to the most intense sunlight provided substances capable of oxidation are absent; if organic substances are present, reduction occurs even in the light from an electric arc; the reduction results in the formation of a brown precipitate or of a green soln. according to the nature of the oxygen acceptor; and gas may be evolved in some cases—*e.g.* ammonia from ammonium chromate. The photosensitiveness of mixtures of gelatine or glue and chromates is of industrial importance—the organic substance becomes insoluble and the chromium trioxide is reduced. J. M. Eder showed that in this respect, the dichromates are more sensitive than the chromates. A. Popovicky suggested that the substance obtained when gelatin treated with a dichromate is exposed to sunlight is the compound, $4Cr_2O_3.3CrO_3$; the tanning action on gelatin is attributed to this compound. J. M. Eder found that the action of light on chromated gelatin begins at $550\mu\mu$, reaches a maximum between $470\mu\mu$ and $430\mu\mu$, and becomes very slight beyond $380\mu\mu$. This is in contrast with J. Plotnikoff's result with collodion sensitized with potassium dichromate and cresyl-blue in which the action was found to begin in the yellow at $595\mu\mu$, and reached a maximum in the green between $540\mu\mu$ and $580\mu\mu$. A photographic reproduction process is based on the reaction; and chromated and insolated glue can in some cases be used as a substitute for wood, leather, or celluloid. According to T. Swensson, the potential of soln. of potassium dichromate against a platinum electrode, and exposed to the ultra-violet light of a mercury lamp, rises rapidly, and on removing the light, it slowly falls. The same result is obtained whether or not the platinum electrode is illuminated. A soln. with 4 mols of sulphuric acid and a mol of potassium dichromate per litre, gives an increase of potential of 0·2280 volt by illumination. The cause of the large change in potential is in some way due to a mutual action of the dichromate and sulphuric acid, since both potassium dichromate soln. and sulphuric acid when submitted alone to the action of the light only give a lowering of the potential, whereas chromic acid soln. gives a slight increase. The increase of potential is independent of the conc. of the soln. E. Müller studied the potential-current curves of 30 per cent. soln. of chromium trioxide, from which it is inferred that a film of chromic oxide is formed at cathode potentials not exceeding 0·3 volt. This film hinders the excess of chromium ions, but is permeable to hydrogen ions. At about —0·7 volt, the film begins to be permeable and an almost continuous reduction of sexivalent to tervalent chromium sets in; and with still more negative values, the deposition of chromium begins, and the film disappears. In the presence of SO_4-, NO_3-, ClO_4-, and SiF_6-ions, the film is imperfect and may be swept away by the gaseous hydrogen which is evolved—hence the presence of sulphates favours the deposition of bright, coherent chromium. The periodic phenomenon in the electrolysis of chromic acid was discussed by J. E. Liebreich, G. J. Sargent, A. Kleffner, and K. Oyabu. A. V. Pamfiloff discussed the *rôle* of chromates in the electroytic production of chlorates; and D. J. MacNaughtan and R. A. F. Hammond, in the electrodeposition of nickel.

According to E. Wedekind and C. Horst,[9] the **magnetic susceptibility** of chromium trioxide is $0{\cdot}75\times10^{-6}$ mass units; K. Honda and T. Sone gave $0{\cdot}51\times10^{-6}$ at 18°, and at 225°, L. Blanc, and L. A. Welo made some observations on this subject. P. Pascal gave $-0{\cdot}5\times10^{-5}$ for the mol. magnetic susceptibility of chromic acid.

§ 14. The Chemical Properties of Chromium Trioxide

According to J. J. Berzelius,[1] and O. Unverdorben, chromium trioxide has no smell; it tastes first acidic, then harsh, but not metallic; and it stains the skin yellow—the stain is not removed by water but it is removed by alkalies. Chromium trioxide solid or in aq. soln., or in sulphuric acid soln., or in the form of its salts, is a strong oxidizing agent, and is therefore reduced by many agents. E. Ludwig observed that **hydrogen** quickly reduces a conc. soln. of chromium trioxide, but acts only slowly on a dil. soln. W. N. Ipatieff and co-workers found that an acidic neutral or alkaline soln. of chromium trioxide at 280° to 300° is reduced by hydrogen under a press. of 200 atm. to form crystals of $Cr_2O_3.H_2O$. In the presence of free sulphuric acid at 300° and 80 atm., small violet-grey crystals, soluble in neither acid nor alkali, are formed and, in the latter case, appear to have the composition $R_2O.2Cr_2O_3.3SO_3.H_2O$. At 280° and 150 to 200 atm., the compound $2Cr_2O_3.3SO_3.6H_2O$ is obtained as dark green, cubic crystals. In the presence of ferrous or ferric sulphate, complex isomorphous mixtures containing iron and chromium are obtained in the form of dark green, cubic crystals. Iron pyrites frequently accompanies such mixtures—*vide supra*, chromic oxyhydroxide. C. L. Reese observed that in the absence of a catalytic agent, a soln. of chromic acid, alone or in the presence of 1 to 15 per cent. by vol. of sulphuric acid, is not reduced by hydrogen below 50°; and only very slowly below 100°. After 116 hrs.' exposure, at 100°, 70 per cent. of hydrogen is oxidized; and at 156°, with 7 hrs.' exposure, 11 per cent. of hydrogen is oxidized and much oxygen is evolved owing to the decomposition of the chromic acid. The oxidation is not dependent on the thermal decomposition of chromic acid because it occurs at a temp. below that at which oxygen is evolved. An aq. soln. of chromic acid is not reduced by the hydrogen evolved by passing an electric current through the liquid, but if a trace of sulphuric acid or a sulphate be present, reduction occurs until a certain limit is reached, and this is dependent on the conc. of the acid. A. C. Chapman found that acidic soln. of chromates are reduced to chromic salts by hydrogenized palladium. J. Hargreaves and T. Robinson observed the reduction of chromates to chromic oxide when heated in hydrogen. Purified chromium trioxide exposed to **air** slowly becomes moist, and deliquescent. A. Mailfert found that in the presence of ether, **ozone** furnishes perchromic acid; but H. Moissan could not obtain blue perchromic acid by the action of ozone on a soln. of chromic acid. Chromium trioxide was found by H. Rose to dissolve in a small proportion of **water** forming a dark reddish-brown soln., and with a larger proportion of water, the colour is lemon-yellow. The aq. soln. reddens litmus. For the solubility in water, *vide supra*. According to M. Traube, in acidic soln., chromium trioxide is reduced by **hydrogen dioxide** to chromic oxide: $4CrO_3+8H_2O_2+6H_2SO_4=2Cr_2(SO_4)_3+7O_2+14H_2O$. L. C. A. Barreswil observed that a transient blue colour is produced before the evolution of oxygen begins—*vide infra*, perchromic acid. The reaction was discussed by A. Bach, E. Spitalsky, A. von Kess and F. E. Lederer, E. Spitalsky and N. Koboseff, and E. H. Riesenfeld and A. Wesch. The catalytic decomposition of potassium dichromate and hydrogen dioxide by cobalt salts is represented: $K_2Cr_2O_7+H_2O_2=2KCrO_4+H_2O$, and $2KCrO_4+H_2O_2=K_2Cr_2O_7+H_2O+O_2$. The velocity of the reaction is promoted by copper, manganese, nickel, and cerium salts. In that case, the reaction $2KCrO_4+H_2O_2=K_2Cr_2O_7+H_2O+O_2$ then gives way to the rapid reaction $2KCrO_4+CoCl_2+2H_2O=H_2CoO_3+K_2Cr_2O_7+2HCl$, and $H_2CoO_3+H_2O_2+2HCl=CoCl_2+3H_2O+O_2$, in agreement with the observation that a definite $H^{\cdot}$-ion conc. is necessary for the promotion. This explanation agrees with the observation that a definite hydrogen-ion conc. is necessary for the promotion. Oxidation of the cobalt is indicated by a decrease in the conc. of the perchromic acid in the promoted reaction. The cobalt may be in the ter- or quadri-valent state during the promotion. The catalytic decomposition of hydrogen dioxide by potassium dichromate was studied by E. Spitalsky and N. Koboseff; and its acceleration by manganese salts by

A. C. Robertson. According to E. Spitalsky and N. Koboseff, during the catalysis of hydrogen dioxide by chromic acid or by acidified soln. of potassium dichromate the conductivity at first decreases sharply to a value which remains approximately constant during the major part of the reaction and then returns to its initial value as the reaction approaches completion. These changes are due to the formation and decomposition of catalytic intermediate compounds, and are, as is the catalysis itself, completely reversible, so that for each initial conc. of the substrate a definite value is obtained for the conductivity decrease and for the minimum conductivity. That the conductivity changes afford a parallel with the complicated kinetics of the reaction in dil. acid soln. is indicated by the coincidence of the maxima of the velocity of catalysis and of the velocity of the conductivity change. From the decrease of the conductivity the extent to which the hydrogen ions are used up in the formation of intermediate compounds may be calculated; the flat portion of the velocity curves represents the complete removal of the hydrogen ions, whilst the velocity maximum expresses their liberation near the end of the reaction. The relationships have been determined at constant substrate conc. of the reaction velocity and of the conductivity decrease with (1) variation of the dichromate conc. at constant acid conc.; (2) variation of the acid conc. at constant dichromate conc.; and (3) variation in constant ratio of both the acid and dichromate conc. In the third case only the reaction velocity and the conductivity decrease are influenced in the same manner by the conc. changes. The nature of the curves obtained leads to the hypothesis that during the course of the reaction two intermediate compounds, M_1 and M_2, are formed reversibly, which require no hydrogen ions for their formation and possess relatively small affinity constants, together with a third compound M_3, which is much more stable and requires hydrogen ions for its formation. From the initial acid and dichromate concentrations and the decrease of hydrogen-ion conc. during the catalysis the most probable nature of the more stable compound M_3 is given by the equation: $2Cr_2O_7''+2H_2O_2+K^{\cdot}+H^{\cdot}=KH_5Cr_4O_{18}''$, the affinity constant of the reaction being 10^{13}. The velocity constants $k_1=42$, and $k_2=5{\cdot}6$. On the flat portion of the velocity curve, where, at high concentrations of hydrogen peroxide, the more stable additive compound M_3 is but little dissociated, the catalysis is effected simultaneously by two intermediate compounds, viz., M_3 and the compound M_1, which is the active agent in the catalysis in neutral soln. Towards the end of the reaction, as the hydrogen peroxide conc. becomes very small, M_3 decomposes and releases the hydrogen ions; very active but short-lived intermediate compounds are then formed, and account for the sharp maximum in the reaction velocity. From the affinity constants of M_1 and M_3, bearing in mind the possible existence of another substance M_2, the reaction velocity curves agree fairly well with part of the experimental curves.

According to H. Moissan,[2] chromium trioxide does not react with **chlorine** free from hydrogen chloride; and K. H. Butler and D. McIntosh observed that the trioxide is insoluble in liquid chlorine, and has no effect on the b.p. of the liquid. According to A. Michael and A. Murphy, a soln. of chlorine in carbon tetrachloride in a sealed tube at 175° forms chromyl and carbonyl chlorides. H. Moissan observed that **bromine** has no action on the trioxide. I. Walz found that a conc. soln. of chromium trioxide, when poured on **iodine,** rapidly turns black and assumes a syrupy consistency, and the liquid thus formed does not respond to the tests for free iodic or hydriodic acid; chromium hypoiodite may be formed. A mixture of sulphuric acid and chromium trioxide oxidizes iodine to iodic acid. O. Ruff and H. Krug found that the trioxide is vigorously attacked by **chlorine trifluoride.** L. Henry showed that **hydrogen chloride** forms chromyl chloride: $CrO_3+2HCl=CrO_2Cl_2+H_2O$. The water so formed reacts with the chromyl chloride producing a dark oily liquid. W. Autenrieth added that the reaction with dry hydrogen chloride is vigorous and chromyl chloride is formed; with 35 to 40 per cent. **hydrochloric acid,** 35 per cent. of the acid forms chromyl chloride: $CrO_3+2HCl=CrO_2Cl_2+H_2O$; with 20 per cent. hydrochloric acid, chlorine, as well as chromyl chloride, is produced:

$2CrO_3+12HCl=2CrCl_3+3Cl_2+6H_2O$. F. Penny said that with boiling hydrochloric acid chromic chloride and chlorine are formed. J. W. Thomas found that hydrogen chloride reduces chromates and dichromates. R. J. Meyer and H. Best obtained chromyl chloride by the action of hydrogen chloride on an acetic acid soln. of chromium trioxide. H. Moissan found that dry **hydrogen bromide** does not act on chromium trioxide; while, according to F. Penny, boiling **hydrobromic acid** yields bromine. M. Bobtelsky and A. Rosenberg found that the velocity measurements agreed with the typical formula for a reaction of the second order; and the effects of salts on the speed of the reaction are summarized in Fig. 27. The action of the salts decreases in the order: $NiCl_2>MgCl_2>FeCl_3>HCl>AlCl_3>CrCl_3$; and $HgCl_2>CdCl_2>ZnCl_2$, where the action of the mercuric chloride is catalytic, and zinc chloride exerts a neutral salt effect. The subject was also discussed by M. Bobtelsky, and by M. Bobtelsky and D. Kaplan. L. L. de Koninck noticed that when potassium bromide is melted with a chromate, bromine is liberated.

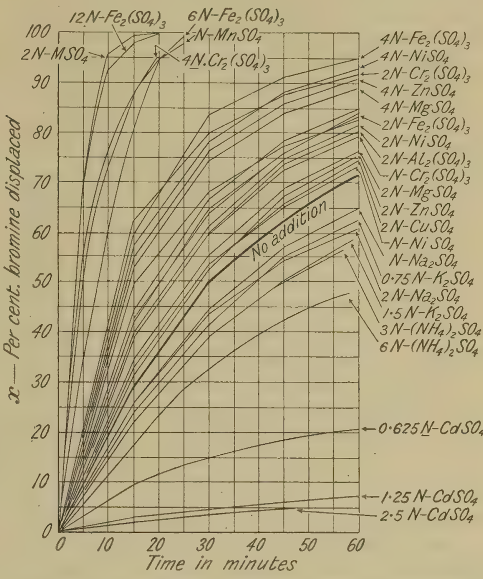

FIG. 27.—The Effect of Salts on the Reaction: $6HBr+2CrO_3=Cr_2O_3+3H_2O+3Br_2$.

H. Moissan found that dry **hydrogen iodide** has no action on chromium trioxide; and F. Penny, C. F. Mohr, E. Donath, and M. M. Richter observed that with boiling **hydriodic acid,** and iodides, iodine is set free. According to W. Ostwald, the reaction $2CrO_3+6HI=2Cr(OH)_3+3I_2$ is accelerated by the presence of free acids proportionally with the affinity constants of the acids. R. E. de Lury found that the velocity of oxidation of potassium iodide by potassium dichromate is proportional to the conc. of the dichromate, and to the square of the conc. of the acid employed. The temp. coeff. of the reaction is about 1·4. The presence of ferric salts strongly accelerates the reaction. The theory of R. Luther and co-workers is that the induction of the reaction between chromic acid and iodides by ferrous salts is due to the formation of quinquevalent chromium by the reaction between ferrous ions and sexivalent chromium ions, these then oxidizing other ferrous ions and also iodide ions. According to C. Wagner and W. Preiss, the equilibrium $Cr^{VI}+Fe^{II}\rightleftharpoons Cr^{V}+Fe^{III}$ is established very rapidly, and C. C. Benson, having shown that the oxidation of ferrous salts by chromic acid is proportional to the square of the conc. of the ferrous salt, said that the reaction between Cr^{V}-ions and $Fe^{\cdot\cdot}$-ions can primarily involve only one of the latter, somewhat as follows: $Cr^{V}+2Fe^{II}\rightarrow Cr^{III}+2Fe^{III}$. The reaction with the iodide ion also proceeds in two stages with hypoiodous acid as an intermediate product: $Cr^{V}+I^{I}+HO^{I}\rightarrow Cr^{III}+HIO$; and $HIO+H^{\cdot}+I'\rightarrow I_2+H_2O$. The values of the velocity cosntants indicate that there is a side reaction involving the splitting up of some Cr^{V}-ions possibly into Cr^{III}- and Cr^{VI}-ions. The reaction was also studied by K. Seubert and J. Carstens, K. Seubert and A. Henke, C. Wagner and W. Preiss, P. A. Meerburg, R. H. Clark, W. Manchot and R. Kraus, R. F. Beard and N. W. Taylor, W. Preiss, A. Schükareff, C. C. Benson, J. M. Bell, W. C. Bray, R. A. Gortner, R. Luther and T. F. Rutter, M. H. Golblum and L. Lew, M. Bobtelsky, and N. A. Orloff. W. B. Morehouse found the X-ray absorption of aq. soln. is greater by 0·25 per cent. after than before the reaction : $K_2Cr_2O_7+12KI+14HCl=8KCl+2CrCl_3+3I_2+6KI+7H_2O$. N. Schiloff studied the catalytic action of chromate ions on the reaction between potassium bromate and potassium iodide. N. R. Dhar showed that the speed of the reaction between chromic acid and potassium iodide is increased in sunlight ; and S. S. Bhatnagar and co-workers, that it is accelerated by a magnetic field. F. E. E. Germann and D. K. Shen studied the action of chromic acid on silver iodide photographic plates.

H. Moissan[3] found that when chromium trioxide is heated with **sulphur,** the mixture inflames, forming sulphur oxides and chromium sulphide. K. Brückner said that chromic oxide and a little sulphide are formed. J. B. Senderens observed that when the mixture is triturated in the cold, sulphur dioxide and a brown mush of chromic chromate and sulphate are formed—if water be present, the reaction does not occur in the cold. According to O. Harten, when **hydrogen sulphide** is passed over heated chromium trioxide, decomposition occurs with incandescence : $2CrO_3+6H_2S=Cr_2S_3+6H_2O+3S$. H. B. Dunnicliff and C. L. Soni studied the mechanism of the reaction, which they represented : $2H_2CrO_4+3H_2S=2Cr(OH)_3+2H_2O+3S$. H. Rose found that an aq. soln. of chromic acid reacts with hydrogen sulphide forming water, sulphur, and hydrated chromic oxide ; aq. soln. of chromates mixed with acid become green when treated with hydrogen sulphide, and sulphur is precipitated ; hot soln. are rapidly decomposed forming sulphuric acid. M. Traube found that dry **sulphur dioxide** does not react with dry chromium trioxide at 100°, and at 180°, sulphur trioxide and chromic chromate are slowly formed. P. Berthier said that aq. soln. of potassium dichromate and chromate are changed rapidly into a mixture of sulphate and dithionate ; with the chromate soln., brown chromium hydroxide is first formed and then dissolved as more sulphur dioxide is passed into the soln. According to H. Bassett, when potassium dichromate, potassium chromate, or chromic acid is reduced by sulphurous acid, 94 to 95 per cent. of sulphate is formed together with 5 to 6 per cent. of dithionate, the amount of the latter produced being independent of the temp. The freshly reduced soln. do not give the reactions of chromium or of SO_4-ions, and appear to contain a compound $(KSO_4)Cr_2(SO_4)_2(KSO_3)$, or the corresponding acid, which slowly decomposes into chromic sulphate and potassium sulphite. If sulphuric acid or potassium sulphate is added to these soln., the reactions of SO_4 are not given by the resulting mixture. It seems possible that one mol of chromium sulphate may mask the reaction of as many as six mols of sulphuric acid. A. Skrabal said that if chromic acid be rapidly reduced by sulphur dioxide an unstable, green chromic salt is formed ; and if slowly reduced with a feebly acid soln., a violet chromic salt is formed. H. Rose found that conc. **sulphuric acid** dissolves chromium trioxide forming, in the cold, a brownish-yellow soln. which gradually deposits crystals of chromium trioxide ; if the soln. is heated to the evaporation temp. of sulphuric acid, oxygen is evolved and chromic chromate and sulphate are formed. A. Wesch observed that when warmed with sulphuric acid, chromium trioxide is decomposed more turbulently than potassium dichromate—oxygen is evolved but no ozone. C. Weltzien, and C. T. Kingzett observed that when conc. sulphuric acid and potassium dichromate are heated together, ozonized oxygen is evolved ; J. C. G. de Marignac denied this. L. I. de N. Ilosva attributed the reaction to the presence of chlorine, not ozone, but R. Kraus found that when powdered potassium dichromate, free from chlorine is triturated with conc. sulphuric acid, ozone is formed. O. Brunck also observed a formation of ozone. A. W. Rakowsky and D. N. Tarassenkoff measured the solubility of chromium trioxide in sulphuric acid between 0° and 100°, and they said that the smooth curves with high concentrations of sulphur trioxide suggest the existence of only one solid phase. A. Schrötter, and P. A. Bolley observed the solubility of chromium trioxide in sulphuric acid respectively of sp. gr. 1·660 and 84·5 per cent. ; and J. Fritzsche found it to be very soluble in sulphuric acid of sp. gr. 1·85. L. F. Gilbert and co-workers found the solubility expressed in molar percentages at 25° to be :

SO_3 .	0	1·47	16·41	32·04	33·17	37·79	38·97	45·80	58·94
CrO_3 .	25·78	21·10	1·11	1·62	1·58	0·43	0·36	0·44	0·88
Solid phase	CrO_3				$CrO_3.SO_3$			$CrO_3.SO_3.H_2O$	

The results are plotted in Fig. 75, in connection with chromyl sulphate. The solubilities at 45° are:

SO_3	5·25	16·73	22·01	31·05	33·55	34·67	37·07	42·26	45·67
CrO_3	13·79	1·00	0·17	1·16	1·15	1·11	0·63	0·38	0·30
Solid phase	CrO_3				$CrO_3.SO_3$				$CrO_3SO_3.H_2O$

The results of A. W. Rakowsky and D. N. Tarassenkoff between 0° and 100°, are plotted in Fig. 28. The hydrate $SO_3.2H_2O$ forms metastable mixed crystals with chromium trioxide. J. Fritzsch said that the trioxide is slightly soluble in a soln. of **potassium hydrosulphate.** According to O. Brunck, chromium trioxide and chromates are immediately reduced by **sodium hyposulphite** at ordinary temp. forming chromic oxide or chromic salts. A. Longi and L. Bonavia observed that in the reaction between chromium trioxide and **thiosulphates,** W. Diehl's equation: $4K_2Cr_2O_7 + 3Na_2S_2O_3 + 13H_2SO_4 = 3Na_2SO_4 + 4Cr_2(SO_4)_3 + 4K_2SO_4 + 13H_2O$ is not correct. On adding a mineral acid and potassium dichromate to a dil. soln. of sodium thiosulphate, A. Longi found that the reaction: $2H_2CrO_4 + 6H_2S_2O_3 = 3H_2S_4O_6 + 2Cr(OH)_3 + 2H_2O$, occurs; small quantities of sulphuric acid are simultaneously formed in accordance with the secondary reaction: $3H_2S_4O_6 + 14H_2CrO_4 + 16H_2O = 12H_2SO_4 + 7Cr_2(OH)_6$. Hydrogen sulphide is also produced, and both sodium thiosulphate and tetrathionic acid give this gas when small quantities of an acid or a chromic salt are added to their soln.; more hydrogen sulphide is obtained at high than at low temp., and tetrathionic acid is more stable than the thiosulphate, for sodium thiosulphate gives hydrogen sulphide when treated with hydrogen dioxide or acetic acid, or when carbon dioxide is passed through its hot soln. The reaction was studied by F. J. Faktor; and G. Powarnin and M. Chitrin showed that in conc. soln., the oxidation proceeds most readily in the absence of an excess of acid—*i.e.* no more than $8H^{\cdot}$ per 2Cr. No more than 4·2 mols of thiosulphate per mol of potassium dichromate take part in the first stage of the reaction; the proportion of sulphur separated increases with the conc. of the $H^{\cdot}$-ions; in neutral soln. no sulphur is formed and the reaction proceeds: $2Cr_2O_7'' + S_2O_3'' = CrO_4'' + 2SO_3'' + 3CrO_2$. When the proportion of $H^{\cdot}$-ions is raised from 8 to 14 per 2Cr, the amount of thiosulphate which undergoes change is altered, and more sulphur is separated. This indicates that when the conc. of the $H^{\cdot}$-ions is low, tetrathionate is formed, and the tetrathionate is decomposed when the conc. of the $H^{\cdot}$-ions is high. H. Moissan observed that **selenium** reacts violently with the trioxide.

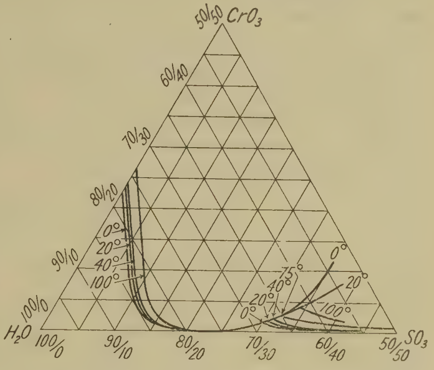

FIG. 28.—The Ternary System: CrO_3–SO_3–H_2O between 0° and 100°.

H. Moissan [4] said that **nitrogen** has no action on chromium trioxide. O. Unverdorben, and R. Böttger showed that **ammonia** gas decomposes the dry trioxide with incandescence at ordinary temp. forming chromic oxide. M. Berthelot examined the heat of the reaction. E. C. Franklin said that the trioxide is slightly soluble in liquid ammonia. According to A. Rosenheim and F. Jacobsohn, liquid ammonia acts on chromium trioxide in a sealed tube at ordinary temp. forming a brown complex-chromium triamminotrioxide, $CrO_3.3NH_3$, or more probably ammonium imidochromate, $NH : CrO(O.NH_4)_2$—*vide* amido compounds, **8**. 49, 21.

For the action of aq. ammonia, *vide* the ammonium chromates. F. Ephraim observed that the trioxide reacts vigorously when triturated with **sodium amide.** T. Curtius and F. Schrader observed that **hydrazine** is decomposed explosively by chromates; U. Roberts and F. Roncali said that 2 mols of potassium dichromate develop 3 mols of nitrogen, while K. Seubert and J. Carstens represented the reaction: $H_2Cr_2O_7+N_2H_4=2CrO_2+3H_2O+N_2$—chromium dioxide is formed as an intermediate product. E. J. Cuy and W. C. Bray represented the reaction with hydrazine in acidic soln. by $3N_2H_5{}^{\cdot}+2Cr_2O_7{}''+13H^{\cdot}=3N_2+4Cr^{\cdot\cdot\cdot}+14H_2O$. E. Schweizer represented the reaction in aq. soln. with **nitric oxide** by: $2K_2Cr_2O_7+2NO=2KNO_3+K_2CrO_4+Cr_2O_3.CrO_3$. The reaction was also studied by H. Reinsch, and C. W. Eliot and F. H. Storer. P. Grouvelle, and F. Wöhler found that **nitrous acid** reduces chromium trioxide in aq. soln. H. Rose said that **nitric acid** does not change the chromic acid of the chromates, but in conc. soln. red fuming nitric acid reduces chromic acid to chromic oxide and brown chromic chromate. E. Zettnow said that chromic acid is insoluble in nitric acid of greater sp. gr. than 1·46; and R. Bunsen, in fuming nitric acid containing no nitrous oxides. S. A. Mumford and L. F. Gilbert found that the solubilities of chromic acid in nitric acid of different conc., when compositions are expressed in grams per 100 grms. of soln., are, at 25°,

HNO_3 .	0	2·28	5·95	13·25	35·35	59·11	74·47	82·90	91·36
CrO_3 .	62·85	60·31	56·47	48·10	25·54	4·88	0·27	0·06	8·29

there is a minimum at 0·06 per cent. CrO_3. At 45°, there is a minimum with 0·44 per cent. CrO_3:

HNO_3 .	0	2·05	5·58	19·53	50·69	73·81	81·55	91·83	98·06
CrO_3 .	53·51	61·27	57·93	43·41	13·15	0·88	0·44	3·39	9·42

The minimum solubility occurs with nitric acid approximating $18N$-HNO_3, or $HNO_3.H_2O$. The curves are simple and continuous. The sp. gr. of the mixed soln. are only approximately additive. H. Moissan observed that **phosphorus** reacts explosively with molten chromium trioxide; and A. Oppenheim found that an aq. soln. of chromic acid at 200° is reduced by red phosphorus to chromic chromate. According to J. Jacobson, phosphorus dissolves in a soln. of chromic acid to form chromic phosphate. E. Kopp observed that a soln. of potassium dichromate when heated, or exposed to sunlight, is reduced by phosphorus. Observations on this subject were made by A. Stiassny, and J. W. Slater—*vide* phosphorus. According to G. Viard, the rate of the reaction between chromic acid and **phosphorous acid** can be represented by $dx/dt=k(a-x)^4$. The initial velocity varies according to a 1·4 power of the concentration. S. S. Bhatnagar and co-workers found that the reduction with phosphorous acid is accelerated by a magnetic field. A. D. Mitchell represented the reaction with **hypophosphorous acid** (*q.v.*): $H_3PO_2+Cr_2O_7{}''=H_3PO_3+Cr_2O_6{}''$; followed by $2H_3PO_2+Cr_2O_6{}''+8H^{\cdot}=2H_3PO_3+2Cr^{\cdot\cdot\cdot}+4H_2O$. *Vide infra*, for the phosphochromates formed by condensation with **phosphoric acid.** H. Schiff represented the reaction with **phosphorus pentachloride** by $CrO_3+PCl_5=CrO_2Cl_2+POCl_3$, and by a secondary reaction, chromic chloride is formed. P. Walden showed that chromium trioxide is virtually insoluble in **phosphoryl chloride.** H. Moissan found that **arsenic** reacts with chromium trioxide with incandescence, forming arsenide. According to C. Reichard, an aq. soln. of chromium trioxide is reduced by **arsenic trioxide**; and the reaction was studied by R. E. de Lury, and W. L. Miller. A. Skrabal showed that if the reaction proceeds slowly, violet chromic salt is formed, and if rapidly, a green salt—*vide* **9**. 51, 22, for the arsenic chromates formed by condensation with **arsenic acid.**

M. Berthelot [5] found that when heated with conc. chromic acid, **carbon** furnishes carbon dioxide and oxalic acid. E. B. Alekseevsky and A. P. Musakin studied adsorption of chromic acid by charcoal. J. Hargreaves and T. Robinson noted that alkali chromates are reduced to chromic oxide by **carbon monoxide,** and an alkali carbonate is formed. B. Neumann and C. Exssner studied the conversion of soln.

of sodium chromate to dichromate by **carbon dioxide** under press. H. E. Armstrong observed that with **carbon disulphide** at 180°, a little carbonyl sulphide is formed; and R. Böttger observed that heated chromium trioxide is reduced by carbon disulphide. I. Guareschi found that **cyanogen bromide** is decomposed by chromic acid, forming bromine, chromic oxide, carbon dioxide, and ammonia. K. Someya studied the electrometric titration of potassium dichromate and potassium ferrocyanide. E. Ludwig observed that **methane** is not attacked by chromium trioxide; while **ethylene** furnishes carbon dioxide, water, formic acid, probably acetic acid, and, according to M. Berthelot, some aldehyde. M. Berthelot also observed that with **acetylene,** a conc. soln. of chromic acid gives carbon dioxide and formic acid, while with dil. soln. some acetic acid is formed; **allylene** yields propionic and acetic acids, etc.; and **propylene,** propionic acid, acetone, etc. R. Fittig found that the side-chains of the **aromatic hydrocarbons** are oxidized to CO.OH groups by chromic acid or a mixture of sulphuric acid and potassium dichromate. According to A. Schafarik, commercial **benzene** inflames in contact with powdered chromium trioxide, but **petroleum,** rectified over sodium, shows scarcely any signs of action after some weeks' contact with chromium trioxide; R. Böttger observed that the heated trioxide is reduced by petroleum or **turpentine.** A. Gawalowsky said that while chromium trioxide and chromates oxidize **alcohol** to aldehyde, a highly purified aq. soln. of chromic acid does not act on alcohol, but it does so if a drop of sulphuric acid be added. J. M. Eder added that a soln. of ammonium dichromate in absolute alcohol decomposes more rapidly than a soln. in 50 per cent. alcohol. The reaction is favoured by light. E. J. Bowen and C. W. Bunn studied the photochemical oxidation of the alcohols—methyl, ethyl, *n*-propyl, and *iso*-propyl—by dichromates. H. Wienhaus observed that chromic esters can be obtained by shaking a soln. of an aromatic tertiary alcohol in light petroleum or carbon tetrachloride with an excess of chromium trioxide. Aromatic secondary alcohols were decomposed by treatment with chromic acid; thymol was coloured blue; and eugenol was oxidized without coloration. S. Takegami observed that colloidal chromic chromate, $Cr(CrO_4)_3$, is formed when alcohol is added to a soln. of chromic acid. E. Müller and co-workers also studied the reaction. B. V. Tronoff and co-workers studied the velocity of oxidation of alcohol; and D. S. Morton examined the photochemistry of the reaction. A. Schafarik said that chromium trioxide is soluble in dried **ether,** freed from alcohol. R. M. Isham and C. E. Vail said that when chromic acid is added to ether, a violent reaction takes place with evolution of acetaldehyde vapour and the separation of green chromic oxide. If the chromic acid is introduced into ether previously cooled to −10°, a yellow soln. is first produced, but oxidation begins almost immediately with the same results as those obtained at the ordinary temp. B. V. Tronoff studied the velocity of oxidation of ethers and **esters.** A. Naumann said that the trioxide is soluble in **acetone.** N. R. Dhar, and G. Ulrich and T. Schmidt studied the reducing action of **formic acid** on chromium trioxide. C. Wagner observed that the reaction with formic acid progresses in stages, $CrO_3 \rightarrow Cr^V \rightarrow Cr^{III}$; and if a manganous salt is present as negative catalyst, $CrO_3 \rightarrow Cr^V \rightarrow 2Cr^{II} + Cr^{III}$. The retarding action of manganous salts on the oxidation of formic or lactic acid by chromic oxide is ascribed to their promoting the transformation of the quinquevalent chromium into sexivalent and tervalent chromium. A. Pictet found that glacial **acetic acid** forms acetochromic acid, $HO.CrO_2.C_2H_3O_2$; and A. Pictet and P. Genequand could not prepare a similar compound with formic acid or with **valeric acid** because of their reducing action; but with **butyric acid,** butyrochromic acid, $HO.CrO_2.C_4H_7O_2$, is formed. The oxidation of **oxalic acid** by chromium trioxide was observed by H. Vohl, W. P. Jorissen and L. T. Reicher, B. K. Mukerji and co-workers, A. K. Bhattacharya and N. R. Dhar, H. Kunz-Krause and P. Manicke, N. R. Dhar, and M. Prud'homme. K. Jablczynsky deduced an equation for the reducing action of oxalic acid on the assumption that it occurs in three stages; $Cr^{VI} \rightarrow Cr^V$ (i), $Cr^V \rightarrow Cr^{IV}$ (ii), and $Cr^{IV} \rightarrow Cr^{III}$ (iii). The velocity constants are respectively k_1=0·0344, k_2=0·1322, and k_3=0·0238. N. R. Dhar found the reaction is about four times as fast in tropical sunlight as in darkness. The reaction was also studied by A. K. Bhattacharya and N. R. Dhar. C. Wagner observed that if a soln. of chromic acid is added to a mixed soln. of potassium iodide and sodium hydrocarbonate, no free iodine is formed, but a reacting mixture of oxalic and chromic acids will liberate appreciable amounts of iodine from the iodide. It is therefore to be concluded that some active intermediate product is formed in the reaction between chromic acid and oxalic acid, and the same is true for the reaction between chromic acid and tartaric acid. This substance is so unstable that it can scarcely be hydrogen peroxide, or a compound, of the nature of percarbonic acid, and attempts to detect the formation of these substances have, in fact, been futile, nor is there any evidence in favour of the existence of chromic acid-oxalic acid complexes. In the reaction between chromic acid and lactic acid, however, the intermediate product is more stable, probably owing to the formation of a complex compound with the lactic acid. Intermediate products are also formed in the oxidation of oxalic, **lactic, tartaric, and thiocyanic acids** by chromic trioxide. Chromium trioxide decomposes tartaric acid, and **citric acid** as observed by W. P. Jorissen and L. T. Reicher, and W. G. Vannoy. A. K. Bhattacharya and N. R. Dhar studied the photochemical decomposition of citric, tartaric, and lactic acids by chromic acid. H. S. Fry found chromium trioxide to be soluble in **acetic anhydride ;** and that **acetyl chloride** dissolved in carbon tetrachloride forms chromyl chloride ; **acetyl bromide** forms chromyl bromide ; but **acetyl iodide** does not react. A. Naumann observed that chromium trioxide is soluble in **benzonitrile,** and in **methyl acetate ;** but is sparingly soluble in **ethyl acetate.** R. Böttger found that ethyl acetate, and **ethyl nitrate** reduce hot chromium trioxide to chromic oxide. M. Prud'homme showed that the oxidation of indigo is greatly accelerated by the presence of oxalic acid. The reducing action of **paper** was observed by A. Maus ; **wool,** by G. Ulrich and T. Schmidt ; **sugar,** by W. P. Jorissen and L. T. Reicher ; **vegetable products,** by J. Jacobson ; **gelatin,** by E. P. Wightman and S. E. Sheppard ; and **animal fibres,** by M. A. Ilinsky and D. I. Kodner. E. Goldberg found that the velocity of the reaction with **quinine** in light is proportional to the intensity of light ; only those rays are active which are absorbed ; Beer's law holds good ; and the temp. coeff. of the reaction is small. R. Luther and G. S. Forbes showed that the quinine is alone sensitive to the light so that the first stage of the reaction is the formation of sensitized quinine with a velocity proportional to the light absorption ; and the second stage is a reaction with the sensitized quinine with a velocity which is proportional to the conc. of the chromic and sulphuric acids. The reaction was studied by D. S. Morton. A. K. Bhattacharya and N. R. Dhar, and B. K. Mukerji and co-workers studied the reaction with quinine sulphate. L. Cohn, and A. Windhaus indicated the use of chromium trioxide in the oxidation of organic compounds in the laboratory, and A. N. Dey and N. R. Dhar studied the kinetics of the oxidation of organic acids by chromic acid. Chromic acid and soluble chromates give precipitates with basic dyes, but not so with the insoluble chromates.

According to P. Lebeau,[6] **silicon** is not attacked by chromium trioxide. R. Bunsen said that chromates heated before the blowpipe flame impart a green colour to beads from **borax,** or **microcosmic salt ;** and L. Möser and W. Eidmann, that **boron nitride** reduces the trioxide to a lower oxide. L. F. Gilbert studied the system CrO_3–B_2O_3–H_2O at 25° and 45°. For the solubility of **boric acid** and chromic acid in grams per 100 grms. of soln., and the sp. gr., he found :

25°	CrO_3 .	62·40	59·90	43·80	33·05	18·07	9·42	4·90
	B_2O_3 .	0·10	0·16	0·65	1·02	1·58	2·28	2·79
	Sp. gr. .	1·699	1·657	1·420	1·296	1·156	1·086	1·052
45°	CrO_3 .	61·56	58·10	57·50	57·34	53·80	25·60	2·40
	B_2O_3 .	0·90	0·92	0·87	0·12	0·85	2·33	4·76
	Sp. gr. .	1·674	1·612	1·603	1·603	1·528	1·219	1·038

J. L. Gay Lussac and L. J. Thénard observed that **sodium** or **potassium** reacts with chromium trioxide with incandescence. R. G. van Name and D. U. Hill found that the values for the monomolecular velocity constant k, in $dx/dt=k(a-x)$, when **copper** dissolves in 0·015 molar soln. of chromium trioxide with 0·05, 0·25, 1·25, and 5·0 molar proportions of sulphuric acid, were, respectively, 5·58, 6·95, 5·34, and 2·072; **silver** and the 0·015 molar chromium trioxide with 0·25, and 5·0 molar H_2SO_4, gave the constants 4·31, and 1·23 respectively. The initial velocity of the dissolution of silver in chromic acid is greater than that which characterizes the normal process of dissolution. This indicates that the velocity depends on the physical state of the metal, and is not entirely determined by the process of diffusion. The reduction of chromic acid by copper was discussed by V. H. Veley,[7] E. Murmann, and F. Fischer. According to R. G. van Name and D. U. Hill, in the action of $0·015M$-CrO_3 and $5·0M$-H_2SO_4 on **tin,** the velocity constant was 2·74; with **nickel,** 2·67; while with **cadmium** and $0·015M$-CrO_3 and 0·25, 1·25, and $5·0M$-H_2SO_4, the velocity constants were, respectively, 7·02, 5·32, and 2·67; and with **iron** and $0·015M$-CrO_3 with 0·25 and $5·0M$-H_2SO_4, the velocity constants were, respectively, 11·68, and 4·20. H. Moissan found that **zinc** reduces chromium trioxide and chromates to chromic oxide or salts; iron also reacts with the evolution of much heat. E. Heyn and O. Bauer observed that iron dissolves in dil. chromic acid, and iron treated with a certain conc. of the chromic acid, may be partially protected from rusting. R. G. van Name and D. U. Hill studied the rate of dissolution of copper, silver, cadmium, tin, and nickel in chromic acid. J. F. John found that **manganese** dissolves in chromic acid. J. Jacobson observed that **mercury** reduces an aq. soln. of chromium trioxide; and also soln. of chromates and dichromates. A. Charriou studied the adsorption of chromic acid by **aluminium hydroxide.** According to A. Scheurer-Kestner, **stannous chloride** is oxidized by chromium trioxide: $6SnCl_2+4CrO_3=3SnCl_4+3SnO_2+2Cr_2O_3$; F. Penny found that dichromates are also reduced by stannous chloride. M. Neidle and J. C. Witt found that the stoichiometric relations in the reaction between stannous chloride and potassium dichromate are the same in the absence of acid as in its presence; when potassium dichromate is added in the theoretical quantity to a soln. of stannous chloride in the absence of acid, brownish- and greenish-blue, gelatinous masses are formed, which dissolve and form a clear, deep olive-green soln. when the whole of the dichromate has been added. These soln. appear red by transmitted light. Dialysis, and extraction with alcohol, showed that the soln. consists of potassium and chromium chlorides, together with colloidal soln. of hydrated stannic and chromic hydroxides. On dialysis a clear sol, of the approximate composition $6SnO_2:1Cr_2O_3$, is obtained, and this sol contains the whole of the tin and about one-half of the chromium used in the reaction. The course of the reaction is given by the equation: $2K_2Cr_2O_7+6SnCl_4+(6x+y+1)H_2O \rightleftharpoons 4KCl+6SnO_2.xH_2O+Cr_2O_3.yH_2O+2CrCl_3+2HCl$. R. Kraus studied the action of soln. of **uranous salts** and **molybdous salts** on chromium trioxide soln.; and K. Someya, soln. of **titanous salts.** A. Geuther represented the reaction with anhydrous **ferric chloride** by: $2FeCl_3+3CrO_3=Fe_2O_3+3CrO_2Cl_2$. S. Orlowsky found that, in alkaline soln., potassium dichromate oxidizes **manganous salts** to manganic: $K_2Cr_2O_7+6MnSO_4+10NH_4OH+7H_2O=2Cr(OH)_3+6Mn(OH)_3+K_2SO_4+5(NH_4)_2SO_4$, and the more conc. the alkali, the smaller the oxidation produced. The reaction was studied by R. Lang and co-workers. For the action on permanganates, *vide* permanganates. Chromium trioxide is reduced by **ferrous salts.** M. Neidle and J. C. Witt found that the stoichiometric relations in the reaction between potassium dichromate and ferrous sulphate are the same in the presence or absence of acid. In the absence of acid the reaction is instantaneous, except in very dil. soln. The reaction may be expressed by the equation: $3K_2Cr_2O_7+18FeSO_4+(x+6y)H_2O=3K_2SO_4+Cr_2O_3.xH_2O+2Cr_2(SO_4)_3+3Fe_2(SO_4)_3+6(Fe_2O_3.yH_2O)$. The colloidal chromic and ferric oxides are precipitated by the sulphate ion in the soln., and adsorb a large quantity of ferric sulphate and smaller quantities of the other two sulphates. The electrometric titration of ferrous salts with potassium dichromate was studied by R. G. van Name and F. Fenwick, and E. Müller and H. Kogert. C. Rube observed that **potassium ferrocyanide** is converted into ferricyanide.

F. Penny, H. Schwarz, and J. Schabus found that a soln. of **ferrous sulphate** gives a yellowish-brown precipitate with chromates or dichromates, which ultimately dissolves and a green soln. of a chromic salt remains. C. C. Benson observed that the rate of oxidation of ferrous sulphate is proportional to the second power of the conc. of ferrous salt and of acid ; and approximately proportional to the 1·7 power of the conc. of the potassium dichromate. The presence of ferric salts retards the reaction. In the presence of iodide, the rate of oxidation of the ferrous salt is proportional to the conc. of the dichromate and ferrous sulphate, and to the third or fourth power of the conc. of the acid. Increasing the conc. of iodide causes at first a decrease and later an increase of the rate. The results are not in accord with the peroxide theory of W. Manchot, which assumes the primary product of oxidation of the ferrous sulphate to be a peroxide, which then reacts with the iodide and the remaining ferrous salt ; but they agree with the assumption that the iodide takes part in the reaction, and the two reactions are suggested as occurring together (i) between Cr_2O_7'', FeI', I', and $4H^{\cdot}$, and (ii) between Cr_2O_7'', $2Fe''$, and $2H^{\cdot}$. The reaction was discussed by W. L. Miller, and R. A. Gortner. The reaction between chromic acid and hydriodic acid in dil. soln. has been studied by N. Schiloff, R. Luther and N. Schiloff, and R. Luther and T. F. Rutter in the presence of hydriodic acid as acceptor, and vanadium salts as inductors. Bi-, ter-, and quadrivalent salts of vanadium are ultimately oxidized to quinquevalent vanadium. The inductor factor is 2, meaning that for one eq. of vanadium oxidized, two eq. of iodine are set free. Vanadic acid does not effect the rate of oxidation of hydriodic acid by chromic acid, and only acts comparatively slowly on hydriodic acid, so that the process is not greatly complicated by side reactions. With uranous sulphate as inductor, and a large excess of potassium iodide, the induction factor is 0·74. While W. Manchot supposed that the inductor is oxidized by chromic acid to a peroxide, R. Luther and T. F. Rutter assumed that the inductor reduces chromic acid to quinquevalent chromium, which is a more rapid oxidizing agent than the acid itself. Whereas W. Manchot's theory requires the formation of intermediate peroxides of very diverse formulæ, the assumption of the intermediate formation of quinquevalent chromium alone accounts for nearly all the reactions so far investigated. It is suggested that the reduction of chromic acid proceeds in the following stages $Cr^{VI} \rightarrow Cr^{V} \rightarrow Cr^{IV} \rightarrow Cr^{III}$, and that chromic acid contains sexivalent and not quadrivalent chromium as W. Manchot has suggested. N. R. Dhar studied some induced reactions, *e.g.* the action of chromic acid on the reduction of mercuric chloride by oxalic acid.

§ 15. The Chromates. Monochromates

The normal chromates are to be regarded as salts of the dibasic **chromic acid,** or rather **metachromic acid,** H_2CrO_4; it is possible that the hypothetical **parachromic acid,** H_4CrO_5, is represented by some of the basic salts—$PbO.PbCrO_4$; and the hypothetical **orthochromic acid,** HCr_6O_6, represented by other basic salts—*e.g.* $2PbO.PbCrO_4$.

L. N. Vauquelin,[1] J. B. Richter, and H. Moser obtained what was regarded as **ammonium chromate,** $(NH_4)_2CrO_4$, by evaporating an aq. soln. of chromic acid mixed with an excess of ammonia. J. J. Pohl said that with the ammonia in large excess, yellow crystals of *ammonium oxychromate,* $(NH_4)_2O.4(NH_4)_2CrO_4$, are formed; which, according to J. Schabus, are monoclinic prisms with the axial ratio $a : b : c = 0·7458 : 1 : 0·4955$, and $\beta = 106° 15'$. C. F. Rammelsberg doubted whether this compound really exists; J. J. Pohl's analysis was imperfect—only the chromium was determined. E. Jäger and G. Krüss showed that when an aq. soln. of chromic acid is evaporated with ammonia, the salt is partially decomposed with evolution of ammonia, and a mixture of chromate and dichromate is always obtained; even when the soln. is evaporated at 50° to 60°, reddish-yellow crystals containing 59·19 per cent. of chromic oxide are obtained, and at ordinary temp., also, a mixture of the two salts is produced. According to Y. T. Gerasimoff, the salt cannot be conveniently prepared by double decomposition, but it can be made by neutralizing chromic acid with ammonia. Ammonium chromate can be prepared by treating chromic acid, free from sulphuric acid, with aq. ammonia of sp. gr. 0·9, adding ammonia and warming gently until the solid salt which separates is redissolved, and then placing the soln. in a freezing mixture. It crystallizes in long, golden needles. E. Maumené said that a conc. soln. of chromic acid or potassium dichromate neutralized by ammonia, deposits ammonium chromate in yellow, crystalline tufts, which resemble those of the potassium salt, but soon lose ammonia, and change into the dichromate. The salt is best crystallized by evaporating the slightly ammoniacal soln. over quicklime, and should be kept in sealed vessels. H. Hirzel obtained ammonium chromate by gradually adding chromyl chloride to an excess of aq. ammonia, and evaporating the soln. below 60°. The first crop of crystals is ammonium chromate; and the next crop, ammonium chloride. The salt was purified by recrystallization. Analyses by E. Kopp, S. Darby, and E. Jäger and G. Krüss agreed with the formula $(NH_4)_2CrO_4$. E. Maumené, L. N. Vauquelin, H. Moser, and E. Jäger and G. Krüss showed that when the aq. soln. of the salt is repeatedly evaporated, it is first converted into the dichromate, and then into a brown oxide. E. Jäger and G. Krüss could not prepare any basic salt like that reported by J. J. Pohl; nor did F. A. H. Schreinemakers observe the formation of any basic salt during his study of the ternary system: CrO_3–NH_3–H_2O, at 30°. The following is a selection from the solubility data for sat. soln.—concentrations are expressed in percentages:

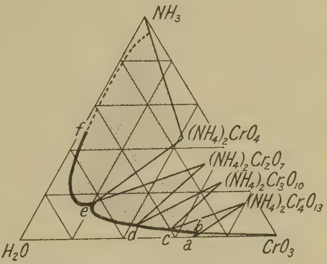

FIG. 29.—Equilibrium Diagram for the Ternary System: CrO_3–NH_3–H_2O at 30°.

CrO_3 . .	6·933	9·966	14·486	18·98	27·09	25·43	42·437

CrO_3 . .	44·08	52·41	56·62	58·87	63·60	62·94	62·28
NH_3 . .	2·271	1·107	0·9496	0·6485	0·3991	0·2094	—
Solids	$(NH_4)_2Cr_3O_{10}$			$(NH_4)_2Cr_4O_{13}$		CrO_3	

The results are shown respectively in Fig. 29. The region above the line *abcdef* refers to unsaturated soln.; *ab* represents soln. in equilibrium with solid chromium trioxide; *bc*, with solid ammonium tetrachromate; *cd*, with solid trichromate; *de*, with solid dichromate; and *ef*, with solid monochromate. Ammonia was here selected as one of the components because $(NH_4)_2O$ is not stable.

According to E. Jäger and G. Krüss, the golden-yellow needles are monoclinic prisms with the axial ratios $a : b : c = 1·9603 : 1 : 2·4452$, and $\beta = 64° \ 47'$. E. Herlinger studied the structure of the crystals. J. W. Retgers said that ammonium chromate is not isomorphous with the potassium chromate family. The other measurements of G. N. Wyrouboff made it appear as if the salt is dimorphous, like potassium chromate ; but more data are required to confirm these results ; however, he found that ammonium chromate forms an isomorphous series of solid soln. with anhydrous, rhombic sodium sulphate, and another series with anhydrous, monoclinic sodium sulphate. There is a gap between the two series, and hence, the salt exhibits what has been called a labile dimorphism. T. Ishikawa studied the system : $(NH_4)_2CrO_4$–$(NH_4)_2SO_4$–K_2SO_4–K_2CrO_4. S. Araki found that the solubility curve in the system : $(NH_4)_2CrO_4$–$(NH_4)_2SO_4$–H_2O at 25° has two branches with two series of solid soln. No solid soln. occur with ammonium sulphate between 2·90 and 21·50 molar per cent.—*BC*, Fig. 30. He also studied the system : $(NH_4)_2CrO_4$–K_2CrO_4–H_2O. H. G. C. Schröder gave 1·866 for the sp. gr. of ammonium monochromate ; F. W. Clarke, 1·917 at 12° ; and E. Jäger and G. Krüss, 1·886, at 11°. K. F. Slotte found the sp. gr. of aq. soln. with 10·52, 19·75, and 28·04 per cent. of $(NH_4)_2CrO_4$ to be respectively 1·0633 at 13°, 1·1197 at 13·7°, and 1·1727 at 19·6° ; and the viscosity (water 100) respectively 108·3, 120·3, and 137·9 at 10° ; 85·2, 95·5, and 110·1 at 20° ; and 57·8, 66·1, and 76·9 at 40°. The sp. ht. of aq. soln. of a mol of ammonium chromate with *n* mols of water was found by J. C. G. de Marignac to be 0·7967 for $n=25$; 0·8767 for $n=50$; 0·9304 for $n=100$; and 0·9630 for $n=200$. The subject was discussed by N. de Kolossowsky. F. Morges gave for the heat of neutralization : $(H_2CrO_{4aq.}, 2NH_4OH_{aq.}) = 22·2$ Cals. at 12° ; and M. Berthelot, 24·42 Cals. at 19·5°. F. Morges also gave $(NH_4)_2Cr_2O_{7aq.}, 2NH_4OH_{aq.}) = 20·4$ Cals. at 12°. P. Sabatier found —5·8 Cals. for the heat of soln. of a mol of ammonium chromate in 200 parts of water at 18°. The spectroscopic observations of D. Brewster, and J. H. Gladstone have been previously discussed. M. G. Mellon studied the colour of soln. of different concentration. I. Plotnikoff and M. Karshulin measured the absorption spectrum and the region of photochemical sensitivity for collodion films with methyl alcohol as acceptor. M. S. Sherrill found the eq. conductivity, λ mho, corrected for hydrolysis, for *m* grm.-equivalents of the salt per litre at 18°, to be .

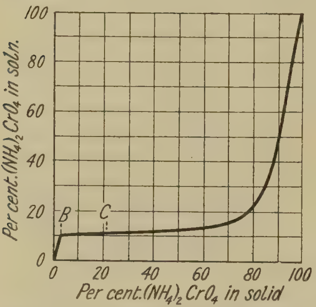

FIG. 30.—Solubility of Binary Mixtures : $(NH_4)_2CrO_4$–$(NH_4)_2SO_4$ at 25°.

m . .	0·005	0·01	0·02	0·04
λ . .	123·4	118·4	112·5	105·5

and C. Watkins and H. C. Jones gave for the molar conductivity, μ mho, of a mol of salt in *v* litres,

v	. .	4	8	16	32	128	512	1024
μ	0° .	99·8	109·3	117·8	126·9	144·0	154·1	152·4
	15° .	146·0	159·7	173·9	187·9	214	227	227
	25° .	—	193·9	213	230	263	280	279
	35° .	—	230	282	274	312	333	333

The calculated percentage ionizations at 0° and 35° are :

v . . .	4	8	16	32	128	512
0° . .	66·7	70·8	76·4	82·3	93·4	100·0
35° . .	—	68·8	75·7	82·2	93·6	100·0

M. S. Sherrill calculated the hydrolysis of a 0·05 molar soln. at 18° to be 2·7 per cent. According to A. Naumann and O. Rücker, a not very exact distillation process showed that the hydrolysis expressed in percentages of the ammonia content, for soln. containing *m* gram-equivalents of salt per litre, was:

m	1·0	0·4	0·1	0·025	0·0025
Hydrolysis	31·0	32·6	36·8	42·0	49·0

E. Jäger and G. Krüss said that ammonium chromate is not particularly stable in the dry state, and on exposure to air, it gradually turns reddish-yellow owing to the formation of the dichromate; it also decomposes in a dry atm., or when gently heated. A. Maus observed that decomposition occurs with glowing, when heated, and the green chromic oxide which remains is readily soluble in acids. W. C. Ball observed that when heated, it decomposes like the dichromate (*q.v.*). According to E. Maumené, ammonium chromate yields a brown oxide, CrO_2, when heated at 204°, identical with the oxide which was described by L. N. Vauquelin as precipitated on heating the aq. soln., although in all probability it is formed only on the superheated sides of the vessel. When the temp. is raised to 220° or 225°, explosive decomposition occurs, and the oxide CrO is formed, which, however, takes fire at once, and burns to the green oxide Cr_2O_3; it is probable that the compound $N_2H_4CrO_3$ is formed as an intermediate product. F. A. H. Schreinemakers found that 40·46 grms. of the salt dissolve in 100 grms. of water at 30°—*vide supra.* In consequence of hydrolysis, the soln., as noticed by L. N. Vauquelin, H. Moser, and E. Jäger and G. Krüss, reacts alkaline, and gradually loses ammonia. Consequently, as pointed out by E. Maumené, it should be crystallized from aq. soln. in an atm. of ammonia. M. Gröger observed that the aq. soln. containing the molar proportions $2NH_3 : CrO_3$ is orange coloured, not yellow. He therefore assumed that the soln. contains a large proportion of dichromate: $2(NH_4)_2CrO_4 \rightleftharpoons 2NH_3+H_2O+(NH_4)_2Cr_2O_7$. C. Paal and G. Brünjes found that in the presence of colloidal palladium, a soln. of ammonium chromate is reduced by hydrogen. W. Müller found that the vapour of carbon disulphide converts it into chromium sulphide and oxide. H. Stamm measured the solubility of the salt in aq. ammonia and found that soln. with 0, 1·818, and 3·436 mols of NH_3 per 100 grms. of water dissolve, respectively, 0·200, 0·066, and 0·043 mol of $(NH_4)_2CrO_4$. E. C. Franklin found that the salt is sparingly soluble in liquid ammonia; and A. Naumann, sparingly soluble in acetone.

G. C. Gmelin,[2] C. F. Rammelsberg, and L. Schulerud prepared **lithium chromate,** $Li_2CrO_4.2H_2O$, by evaporating an aq. soln. of lithium carbonate in chromic acid. J. W. Retgers said that if the soln. be evaporated at this temp., or if the salt be heated to 150°, the anhydrous salt is formed, and it consists of needle-like crystals probably isomorphous with anhydrous lithium sulphate. F. Mylius and R. Funk said that a soln. of the salt sat. at 18° contains 52·6 grms. of Li_2CrO_4 per 100 grms. of water; W. Kohlrausch said that 100 c.c. of soln. at 18° contain 85 grms. Li_2CrO_4; P. P. von Weimarn, 100 grms. of water at 20° dissolve 111 grms. of salt, and F. A. H. Schreinemakers said 99·94 grms. at 30°. The salt deposited from its aq. soln. is the *dihydrate*, $Li_2CrO_4.2H_2O$, as proved by the analyses of C. F. Rammelsberg, and L. Schulerud. F. A. H. Schreinemakers observed that the ternary system: $Li_2O–CrO_3–H_2O$, at 30°, contains the following percentage proportions of lithium oxide and chromium trioxide:

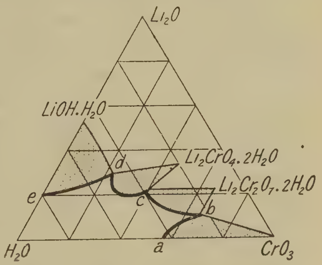

FIG. 31.—Equilibrium Diagram for the Ternary System: $Li_2O–CrO_3–H_2O$ at 30°.

CrO_3	—	22·51	37·50	38·55	43·40	49·60	67·73	63·26	62·28
Li_2O	7·09	9·88	16·34	11·44	11·81	7·33	5·69	2·14	—
Solids		$LiOH.H_2O$		$Li_2CrO_4.2H_2O$		$Li_2Cr_2O_7.2H_2O$		CrO_3	

The results are summarized in Fig. 31; the curve *ab* refers to soln. in equilibrium with solid chromium trioxide; *bc*, with solid $Li_2Cr_2O_7.2H_2O$; *cd*, with solid $Li_2CrO_4.2H_2O$; and *de*, with solid $LiOH.H_2O$. G. C. Gmelin said that lithium chromate furnishes orange-yellow, rhombic prisms, or dendritic masses, which, according to C. F. Rammelsberg, have the axial ratios $a:b:c=0·662:1:0·466$. F. Mylius and J. von Wrochem found that the soln. sat. at 18°, has a sp. gr. 1·574; A. Heydweiller gave for the sp. gr. of gram-equivalent soln. at 18°/18°,

	0·0815N-	0·1629N-	0·4115N-	0·823N-	2·057N-	4·115N-
Sp. gr. . .	1·00458	1·00902	1·02052	1·04437	1·10746	1·20659

C. F. Rammelsberg said that the salt is deliquescent, but when confined over conc. sulphuric acid, it effloresces; and, added L. Schulerud, it loses its water of crystallization at 130°, and melts at a higher temp. P. P. von Weimarn added that when the molten mass is rapidly cooled, it furnishes a transparent glass. G. Tammann found that 4·63, 20·23, 41·93, and 59·09 grms. of lithium chromate in 100 grms. of water lower the vap. press. respectively 11·5, 53·6, 131·2, and 205·2 mm. A. Heydweiller found the indices of refraction of 0·1, 0·5, 1·0, and 4·0N-Li_2CrO_4 are respectively 1·33529, 1·34307, 1·35251, and 1·40612 for the *D*-line at 18°; and the eq. electrical conductivities, λ mhos, of 0·0815, 0·4115, and 4·115N-soln. are respectively $\lambda=76·02$, 59·67, and 22·73 at 18°. C. Watkins and H. C. Jones gave for molar conductivity, μ mhos, for a mol of salt in v litres of water,

v	. . .	8	16	32	128	512	1024	2048
μ	0° . .	80	88	96	108	113	115	122
	15° . .	120	132	146	165	175	177	179
	25° . .	149	164	181	206	129	220	223
	35° . .	180	200	219	252	265	267	268

The percentage ionizations at 0° and 35° are:

v . .	8	16	32	128	512	1024	2048
0° . .	65·4	72·4	78·7	89·0	93·2	94·7	100·0
35° . .	67·2	74·5	81·7	94·0	99·0	99·5	100·0

H. Traube said that complex **lithium potassium sulphatochromate,** $Li_2CrO_4.K_2SO_4$, furnishes hexagonal crystals. C. F. Rammelsberg prepared what he regarded as **ammonium lithium chromate,** $(NH_4)LiCrO_4.2H_2O$, in non-deliquescent crystals from a soln. of the component salts.

Methods indicated in connection with the extraction of chromium from chromite can be made to yield **sodium chromate,** Na_2CrO_4. H. Moser[3] obtained it by fusing chromite with sodium hydroxide and nitrate, and crystallizing from an aq. soln. of the cold cake; and H. Kopp, by fusing chromic oxide with sodium nitrate, etc. J. d'Ans and J. Löffler obtained the chromate amongst the products of the action of chromic oxide on sodium hydroxide. M. R. Nayer and co-workers found that sodium carbonate and chromic oxide readily interact to form chromate at temp. below 660°; the salt melts at 800° and remains undecomposed after prolonged heating at 1000°. Ferric oxide and, to a greater extent, calcium oxide, accelerate the formation of chromate in mixtures of sodium carbonate and chromic oxide by preventing the mass from fusing and thus allowing better access of air. H. Moser obtained sodium chromate by neutralizing a soln. of chromic acid with sodium carbonate; and S. W. Johnson, by saturating a soln. of potassium dichromate with sodium carbonate and crystallizing the liquid. The salt can be so obtained free from potassium salts. M. de K. Thompson and co-workers, and A. J. B. Jouve and A. Helbronner obtained sodium chromate by electrolyzing sodium hydroxide soln. with ferrochromium anodes. If the aq. soln. be evaporated above 30°, H. Kopp, and J. W. Retgers said that the anhydrous salt is obtained; H. Traube gave 60° to 70°. Actually, the transition temp. is near 68°, Fig. 33. T. W. Richards and G. L. Kelley gave 62·8°. H. Traube added that the *dihydrate*, $Na_2CrO_4.2H_2O$, reported by G. N. Wyrouboff, is the imperfectly-dried, anhydrous salt.

J. W. Retgers said that the anhydrous sodium chromate forms yellow, columnar crystals, probably rhombic, and not isomorphous with sodium sulphate; H. Traube said that the two salts are isomorphous; and gave for the rhombic, bipyramidal crystals the axial ratios $a : b : c = 0·4643 : 1 : 0·7991$. The (010)-cleavage is perfect. J. Traube and W. von Behren studied the crystallization of the salt. E. Flach showed that sodium chromate and sulphate are completely miscible and isomorphous. The effect of the sulphate on the transition points of the chromate is illustrated by Fig. 32. C. Leenhardt studied the speed of crystallization of the hydrates.

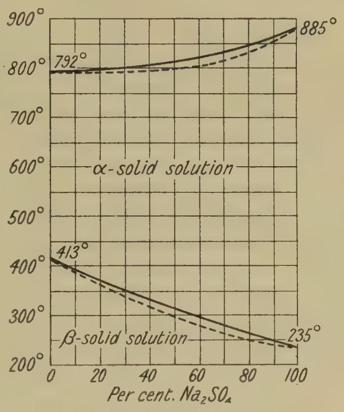

FIG. 32.—Effect of Sodium Sulphate on the Freezing and Transition Points of Sodium Chromate.

The existence of three hydrates has been established. F. W. Clarke gave 2·710 to 2·736 for the sp. gr.; and I. Traube added that the drop weight of the salt, at its m.p., is 328·2. The *tetrahydrate*, $Na_2CrO_4.4H_2O$, was prepared by D. Gernez by evaporating a supersaturated soln. of the decahydrate, or by contact of the soln. with the anhydrous salt. H. Traube obtained it from a conc soln. at 50°; and G. N. Wyrouboff, at 25° to 29°. J. Zehenter neutralized a soln. of potassium dichromate with sodium carbonate, and crystallized the mother-liquor after the separation of the $3K_2CrO_4.Na_2CrO_4$. The sulphur-yellow, acicular crystals were found by H. Traube to be monoclinic prisms with the axial ratios $a : b : c = 1·1112 : 1 : 1·0624$. E. Herlinger studied the structure of the crystals. T. W. Richards and W. B. Meldrum observed the formation of isomorphous mixtures of $Na_2SO_4.4H_2O$ and $Na_2CrO_4.4H_2O$. L. Delhaye measured the optical properties of the monoclinic crystals of the tetrahydrate prepared by allowing a soln. of sodium chromate, sat. at 50°, to cool to about 27°, filtering, and keeping for several days with occasional shaking. He gave for the optic axial angle $2V = 30° 50'$ for $\lambda = 462\mu\mu$; $29° 52'$ for $\lambda = 502\mu\mu$; $25° 33'$ for $\lambda = 536\mu\mu$; $21° 49'$ for $\lambda = 563\mu\mu$; and $16° 56'$ for $\lambda = 582\mu\mu$; and for the indices of refraction,

λ	535	573	589	600	625	650	670$\mu\mu$
α	1·576	1·566	1·561	1·559	1·551	1·545	1·536
β	1·471	1·457	1·447	1·440	1·383	1·291	1·285
γ	1·342	1·328	1·321	1·317	1·308	1·297	1·221

G. N. Wyrouboff gave for the optic axial angle $2E = 16° 10'$ for red-light, and 36° 22′ for green-light; he also said that the salt is somewhat deliquescent, and loses 2 mols. of water at 110°, and the rest at 250°; while H. Traube said that the salt loses water if allowed to stand in air for some time, and all the water is expelled at 150°. F. Mylius and R. Funk gave for the percentage solubility of the tetrahydrate—stable between 25·9° and 68°, Fig. 33—

	25·6°	36·0°	45·0°	54·5°	65·0°
S	46·08	47·98	50·20	52·28	55·23

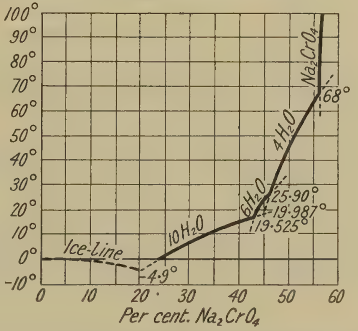

FIG. 33.—Solubility Curve of Sodium Chromate.

H. Salkowsky obtained the *hexahydrate*, $Na_2CrO_4.6H_2O$, accidentally from the mother-liquors of a soln. out of which the salt, $Na_2CrO_4.4H_2O$, had been crystallized. It crystallized in triclinic plates, and further crops were obtained by seeding sat. soln. of sodium chromate with it.

The percentage solubility of the hexahydrate—stable between 19·526° and 25·90°, Fig. 33—is:

	17·7°	19·2°	21·2°	24·7°	26·6°
S . . .	43·65	44·12	44·64	45·75	46·28

The *decahydrate*, $Na_2CrO_4.10H_2O$, is the salt obtained when the soln. is crystallized at ordinary temp., and it is the form stable below 19·526°. The crystals obtained by H. Moser, and J. F. John were lemon-yellow, and had a rough, metallic taste, and alkaline reaction. H. J. Brooke found that the monoclinic crystals, isomorphous with decahydrated sodium sulphate, have the axial ratios $a:b:c$ $=1·1127:1:1·2133$, and $\beta=107°\ 43'$; V. Rosiczky gave 1·1038 : 1 : 1·2351, and $\beta=72°\ 28°$. I. Takeuchi thought that a definite sodium trisulphatochromate, $2Na_2SO_4.Na_2CrO_4.30H_2O$, was formed at 25°, but Y. Osaka and R. Yoshida found that it is not a definite compound. Rather is it a solid soln. No solid soln. exists at 33°. At 28° and 31°, the chromate exists as the tetrahydrate and its solubility in the sulphate as the decahydrate decreases as the temp. rises, the molar fraction being 0·16 at 28° and 0·04 at 31°. G. N. Wyrouboff gave for the optical axial angle of the decahydrated chromate $2Y=83°\ 56'$ for red-light, and 82° 20′ for green-light. F. W. Clarke gave 1·483 for the sp. gr., and V. Rosiczky, 1·526. H. Kopp said that the crystals melt by the heat of the hand; S. W. Johnson gave 20°–21° for the m.p.; W. A. Tilden, and M. Berthelot gave 23°; J. L. R. Morgan and H. K. Benson, 19·92°; and F. Mylius and R. Funk said that there is a congruent m.p. at 21°. The m.p. lies in the region of instability of the hydrate since at 19·525°, there is a transformation into the hexahydrate with partial melting. T. W. Richards and G. L. Kelley suggested this incongruent m.p. as a fixed point in thermometry. G. Tammann found that the transition temp., θ, for $Na_2CrO_4.10H_2O \rightleftharpoons Na_2CrO_4.6H_2O + 4H_2O$, is lowered by an increase of press. p kgrms. per sq. cm., so that:

p . . .	1		400		600		1000		2300		3050
θ . . .	19·60°		18·50°		17·50°		14·90°		7·00°		0·00°
dp/θ . .		350		200		150		165		110	

This agrees with R. Hollmann's observations that the decahydrate contracts on fusion 0·010 c.c. per gram of salt. H. J. Brooke, and T. Thomson said that the crystals effloresce very rapidly in cold, dry air; and, added H. Moser, they become moist only in a damp. atm. H. Lescoeur found that the vap. press. of the sat. soln. is 10·6 mm. at 20° so that if the partial press. of the water-vapour in atm. air exceeds this, the salt will be deliquescent. F. Mylius and R. Funk found the percentage solubility of the decahydrate—stable below 19·256°—is:

	0°	10·0°	18·5°	19·5°	21·0°
S . . .	24·04	33·41	41·65	44·78	47·40

Observations on the solubility were made by F. Kohlrausch, F. Mylius and R. Funk, I. Takeuchi, and H. Salowsky. T. W. Richards and co-workers gave for the transition point between the decahydrate and the hexahydrate 19·525° to 19·63° with 44·2 per cent. Na_2CrO_4; T. W. Richards and R. C. Wells, 26·6°; T. W. Richards and G. L. Kelley gave 25·90° and H. Salkowsky 26·6° with 46·3 per cent. Na_2CrO_4 for the transition point between the hexahydrate and the tetrahydrate; and F. Mylius and R. Funk, about 68° with 55·2 per cent. Na_2CrO_4 for the transition temp. between the tetrahydrate and the anhydrous salt. J. Zeltner gave −4·9 for the eutectic temp. between ice and the decahydrate. The percentage solubilities can be summarized:

	0°	10°	19·525°	21·2°	25·90°	40°	68°	80°	100°
S . . .	24·1	33·4	44·2	44·6	46·3	49·0	55·2	55·3	55·8
	$Na_2CrO_4.10H_2O$			$Na_2CrO_4.6H_2O$		$Na_2CrO_4.4H_2O$		Na_2CrO_4	

The results are plotted in Fig. 34. There is a metastable region; F. Mylius and R. Funk gave for the solubility in this region 47·4 per cent. Na_2CrO_4 at 21° with the decahydrate as solid phase ; and the transition point 19·987° for the decahydrate and tetrahydrate. E. W. Washburn and E. R. Smith gave 19·51 for the transition temp. F. A. H. Schreinemakers observed that in the ternary system : Na_2O–$CrO_3.H_2O$ at 30°, when concentrations are expressed in percentages,

CrO_3 .	0	2·0	10·21	10·22	10·74	19·26	28·82	48·70
Na_2O .	42·0	41·44	29·70	29·39	25·55	22·98	17·88	16·49
Solids	$NaOH.H_2O$		Na_2CrO_4		$Na_4CrO_5.13H_2O$		$Na_2CrO_4.4H_2O$	

CrO_3 .	48·70	55·09	66·13	67·37	68·46	66·88	65·72	64·43
Na_2O .	16·49	14·44	13·70	12·50	10·95	9·85	6·31	4·51
Solids		$Na_2Cr_2O_7.2H_2O$		$Na_2Cr_3O_{10}.H_2O$	$Na_2Cr_4O_{15}.4H_2O$		CrO_3	

The solubility curve *ab* refers to the solid phase chromic acid; *bc*, to $Na_2Cr_4O_{13}.4H_2O$; *cd*, to $Na_2Cr_3O_{10}.H_2O$; *de*, to $Na_2Cr_2O_7.2H_2O$; *ef*, to $Na_2CrO_4.4H_2O$; *fg*, to $Na_4CrO_5.13H_2O$; *gh*, to Na_2CrO_4 ; and *hi*, to $NaOH.H_2O$. The basic salt, **sodium oxychromate,** $Na_4CrO_5.13H_2O$, or $Na_2O.Na_2CrO_4.13H_2O$, was obtained by F. Mylius and R. Funk from an aq. soln. of chromium trioxide sat. with sodium hydroxide. The pale-yellow crystals melt at 50° with the separation of sodium chromate. The aq. soln. saturated at 18° contains 37·5 per cent. of the anhydrous salt, and has a sp. gr. 1·446 ; and in soln. the salt is probably hydrolyzed. F. A. H. Schreinemakers said that it dissolves undecomposed in water, and the aq. soln. at 30° has 41·3 per cent. of the salt. F. Mylius and R. Funk gave for the percentage solubility :

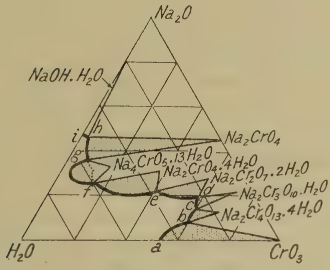

FIG. 34.—Equilibrium Diagram for the Ternary System : Na_2O–CrO_3–H_2O at 30°.

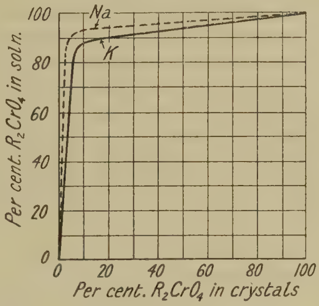

FIG. 35. — Crystallization of Mixed Solutions of Alkali Chromates and Sulphates.

	0°	10°	20·5°	27·7°	35°	37°
S . .	33·87	35·58	38·05	40·09	44·09	45·13

E. Flach studied the equilibrium between mixed soln. of sodium chromate and sulphate at 70° and the results are summarized in Fig. 35. With soln. containing 22, 62, 82, 91·5, and 96·5 per cent. of Na_2CrO_4, the separated crystals had, respectively, 0·21, 1·79, 3·45, 10·99, and 62·91 per cent. Na_2CrO_4 ; 99·16, 96·14, 94·58, 84·43, and 31·50 per cent. Na_2SO_4 ; and 0·63, 2·07, 1·99, 4·58, and 5·59 per cent. of water.

F. Mylius and R. Funk gave 1·409 for the sp. gr. of a soln. sat. at 18° ; A. Heydweiller, for soln. with 0·0533, 0·1066, 1·066, and 2·132 mols Na_2CrO_4 per litre at 18°, respectively 1·0077, 1·0152, 1·1442, and 1·2758 ; and H. C. Jones and H. P. Bassett, for soln. at 18°,

Na_2CrO_4 .	0·81	1·60	3·15	6·14	8·98	11·69	14·28 per cent.
Sp. gr. .	1·0075	1·0152	1·0287	1·0561	1·0834	1·1100	1·1366 ,,

K. F. Slotte found the sp. gr. of aq. soln. containing 5·76, 10·62, and 14·81 per cent. sodium chromate to be respectively 1·0576 at 17·4°/4°, 1·1125 at 17·1°/4°, and

1·1604 at 20·7°/4° ; and the viscosities (water 100), respectively at 10°, 117, 140·9, and 174 ; at 20°, 90·8, 108·3, and 132·5 ; at 30°, 72·8, 86·6, and 105·5 ; and at 40°, 59·8, 71·3, 85·9. J. L. R. Morgan and E. Schramm gave for the surface tension θ dynes per cm. :

Na_2CrO_4 .	4·45	12·67	24·05	34·91	45·25	49·81	53·13 per cent.
θ . .	71·64	73·35	76·48	81·52	89·73	95·36	97·46 ,,

For the observations of L. J. Simon on the viscosity of the soln. *vide infra*, potassium chromate. J. J. Coleman found that normal soln. of sodium molybdate, chromate, and tungstate diffused so that respectively 28, 25, and 17 per cent. rose 75 mm. in 30 days at 12·5°. J. C. G. de Marignac found for the sp. ht. between 21° and 52°, for soln. with 25, 50, 100, and 200 mols of water per mol of Na_2CrO_4, respectively 0·7810, 0·8560, 0·9134, and 0·9511. The subject was discussed by N. de Kolossowsky. G. Tamman observed the lowering of the vap. press. for soln. with 7·50, 30·88, 47·19, and 72·43 grms. of Na_2CrO_4 per 100 grms. of water, respectively 13·3, 61·6, 102·2, and 159·3 mm. of mercury—*vide supra*, for H. Lescoeur's observation. H. C. Jones and H. P. Bassett found the lowering of the f.p. for soln. with 0·1, 0·3, 0·6, and 1·0 mols of Na_2CrO_4 per litre to be respectively 0·450°, 1·230°, 2·345°, and 3·800°. F. Morges gave for the heat of neutralization of aq. soln. $(H_2CrO_4,2NaOH)$ =23·67 Cals. at 18° ; J. Thomsen, $(H_2CrO_4(400\text{ aq.}),2NaOH(400\text{ aq.}))$=24·72 Cals., or, according to M. Berthelot, 28·72—30(θ—18) Cals. at θ° ; and $2H_2CrO_4(800\text{ aq.})+8NaOH(1600\text{ aq.})\rightarrow 2Na_2CrO_4\text{ aq.}+4NaOH\text{ aq.}$+50·328 Cals. at 18°. W. G. Mixter gave for the heat of formation : $Cr+3Na_2O_2=Na_2CrO_4+2Na_2O$+158·8 Cals. ; $Cr_2O_{3\text{cryst.}}+3Na_2O_2=2Na_2CrO_4+Na_2O$+108·0 Cals. ; and (CrO_3,Na_2O)=77·0 Cals. M. Berthelot found for the heat of soln., Na_2CrO_4 with 360 to 720 mols of water, 2·2 Cals. at 10·5° ; $Na_2CrO_4.4H_2O$ with 650 mols of water, —7·6 Cals. at 11° ; and $Na_2CrO_4.10H_2O$ with 760 mols of water, —15·8 Cals. at 10·5°. Accordingly, the heat of hydration is $(Na_2CrO_{4\text{solid}},10H_2O_{\text{liquid}})$=18·0 Cals. at 10·5° ; and the heat of fusion of the decahydrate is —12·3 Cals. at 10·5°, and —13·4° Cals. at 23°. A. Heydweiller found the eq. conductivity, λ mhos, at 18° for 0·1066N-, 0·533N-, 1·066N-, and 4·264N-soln. to be, respectively, 81·84, 65·73, 56·96, and 29·05. R. Lenz, and H. C. Jones and H. P. Bassett made some observations on this subject, and C. Watkins and H. C. Jones gave for the mol. conductivity, μ mhos, for a mol of salt in v litres of water :

v	. .	4	8	16	32	128	512	1024
μ	0° .	74·76	83·56	90·74	98·16	110·40	118·32	114·60
	15° .	113·4	125·3	137·8	148·6	168·4	176·2	173·6
	25° .	—	156·5	171·3	185·1	206·7	219·5	216·9
	35° .	—	187·9	207·6	224·3	252·2	270·1	262·3

The percentage ionizations at 0° and 35° are :

v . . .	4	8	16	32	128	512
0° . . .	63·2	70·6	76·7	82·9	93·3	100·0
35° . . .	—	69·6	76·8	83·0	93·4	100·0

A. Berthoud observed no maximum in the conductivity curve. P. Düllberg studied the electrometric titration with hydrochloric acid. For the electrolysis of soln. of the chromate, *vide infra*, sodium dichromate. H. Ollivier studied the paramagnetism of the salt. H. Stamm measured the solubility of the salt in aq. ammonia, and found that soln. with 0 and 3·3079 mols NH_3 per 100 grms. of water dissolve 0·3595 and 0·1147 mol Na_2CrO_4, respectively. B. Neumann and C. Exssner studied the conversion of sodium chromate to dichromate on aq. soln. by carbon dioxide under press. J. F. John, and H. Moser said that the decahydrate is sparingly soluble in alcohol ; C. A. L. de Bruyn found 100 grms. of absolute methyl alcohol dissolve 0·345 grm. of Na_2CrO_4 at 25° ; and A. Naumann observed the salt to be insoluble in acetone. F. E. Brown and J. E. Snyder observed no reaction with boiling vanadium oxytrichloride and anhydrous sodium chromate.

L. Kahlenberg and W. J. Trautmann observed no reaction when the chromate is mixed with silicon and heated in a hard glass tube by a bunsen burner, but a strong reaction occurs when heated by a Méker burner. J. Zehenter precipitated **ammonium sodium chromate,** $(NH_4)NaCrO_4.2H_2O$, by adding alcohol to a mixed soln. of ammonium chromate and sodium carbonate; and G. N. Wyrouboff, from a mixed soln. of ammonium and sodium chromates. The rhombic, prismatic crystals are said to be isomorphous with the corresponding sulphate, the axial ratios are $a : b : c = 0{\cdot}4780 : 1 : 0{\cdot}8046$; the optical character is negative; and the optic axial angles for red and green light respectively are $2H_a = 93° \ 15'$ and $80° \ 15'$; $2H_0 = 108° \ 0'$ and $129° \ 30'$; and $2V = 83° \ 52'$ and $70° \ 56'$. According to J. Zehenter, the sp. gr. is 1·842 at 15°. The salt decomposes between 150° and 180° with the evolution of water and ammonia. The aq. soln. made just turbid with alcohol decomposes in light.

According to A. Raimondi,[4] the yellow mineral **tarapacaite** from the province of Tarapaca, Chili, occurs in the midst of the variety of soda-nitre called *caliche azufrado.* It is essentially a **potassium chromate,** K_2CrO_4, mixed with a little sodium chloride, nitrate, and sulphate, and potassium sulphate. I. Domeyko also observed its occurrence in the desert of Atacama, Chili. The preparation of potassium chromate has been discussed in connection with the extraction of chromium. T. Thomson, and J. von Liebig and F. Wöhler obtained it from the soln. obtained by neutralizing potassium dichromate with the carbonate. J. von Liebig and F. Wöhler converted chromic oxide into chromate by ignition with potassium chlorate; and V. Kletzinsky, fused potassium dichromate with the nitrate. N. J. Berlin purified the chromate by treating a soln. of the dichromate with a soln. of barium chromate in chromic acid; evaporated to dryness a mixture of the filtrate with an excess of potassium carbonate; and crystallized the product from aq. soln. until it was nearly free from alkali carbonate; digested the aq. soln. with silver chromate; and crystallized and recrystallized the chromate from the filtrate by spontaneous evaporation.

No hydrates are formed under ordinary conditions. Observations on the solubility of potassium chromate were made by T. Thomson, A. Michel and L. Krafft, H. Moser, M. Alluard, A. E. Nordenskjöld and G. Lindström, A. Étard, C. von Hauer, W. Kohlrausch, P. Kremers, M. Amadori, H. Schiff, K. F. Slotte, I. Koppel and E. Blumenthal, F. Flöttmann, and F. A. H. Schreinemakers. The general results show that the percentage solubility, S, is:

	−11·33°	−5·75°	0°	10°	20°	40°	60°	80°	100°	105·8°
S .	23·1	36·6	36·7	37·9	38·6	40·1	42·1	42·9	44·2	47·0

F. Flöttmann found the solubility at 15°, 20°, and 25° to be 2·725, 2·764, and 2·799 mols per litre, or 38·49, 38·94, and 39·38 per cent., respectively. The eutectic temp., ice and K_2CrO_4 is, according to L. C. de Coppet, —11·30° with 36·6 per cent. of salt; according to F. Guthrie, —11·00° and 36·3 per cent. of salt; and, according to I. Koppel and E. Blumenthal, at —11·70 and 35·3 per cent. of salt.

E. H. Riesenfeld and A. Wesch treated a conc. aq. soln. of $K_5[(CrO_4)_2Cy_5).5H_2O$ with alcohol; a red oil is precipitated. This is separated and covered with alcohol, and allowed to stand for some days in a calcium chloride desiccator, and purified by recrystallization. The analysis agrees with the *tetrahydrate,* $K_2CrO_4.4H_2O$. The pale yellow prisms gradually lose water, and they are slightly hygroscopic. The aq. soln. is neutral, and it is darker than that of ordinary potassium chromate, and paler than the dichromate.

The ternary system: $K_2O–CrO_3–H_2O$ at 30° was studied by F. A. H. Schreinemakers, who found for the percentage solubilities:

CrO_3 . . .	0	0·18	5·6	20·67	10·43	46·46
K_2O . . .	47	34·6	20·58	19·17	4·91	3·25
Solids		$KOH.2H_2O$	K_2CrO_4		$K_2Cr_2O_7$	
CrO_3 . . .	44·46	47·65	49·73	55·83	63·14	62·28
K_2O . . .	3·25	2·67	2·25	0·87	0·56	—
Solids		$K_2Cr_3O_{10}$		$K_2Cr_4O_{13}$	CrO_3	

The results are plotted in Fig. 36; where the solubility curve *ab* has the solid phase CrO_3; *bc*, potassium tetrachromate; *cd*, trichromate; *de*, dichromate; *ef*, chromate; and *fg*, $KOH.2H_2O$. I. Koppel and E. Blumenthal's results at 0°, 30°, and 60° are summarized in Figs. 37, 38, and 39. As before, *ab* represents the region when the solid phase is CrO_3; *bc*, $K_2Cr_4O_{13}$; *cd*, $K_2Cr_3O_{10}$; *de*, $K_2Cr_2O_7$; *ef*, K_2CrO_4; and *fg*, $KOH.4H_2O$ at 0°; $KOH.2H_2O$ at 30°; and $KOH.H_2O$ at 60°. The results are collected together in the model, Fig. 41, where the area gg_0f_0f refers to the hydrates of potassium hydroxide; f_0fee_0, to K_2CrO_4; e_0edd_0, to $K_2Cr_2O_7$; d_0dcc_0, to $K_2Cr_3O_{10}$; c_0cbb_0, to $K_2Cr_4O_{13}$; b_0baa_0, to CrO_3; $gfedcbaO$, to ice; and the area $g_0f_0E'_0e_0E_0d_0c_0b_0a_0(O_0)$, to the region where the vap. press. is 760°. $E'E'_0$ and EE_0 are eutectic lines. The b.p. for f_0 is 109°; E'_0, 105° 8°; e_0, 106·8°; E_0, 104·8°; d_0, 114·0°; and a_0, 127·0°. W. Herz and F. Hiebenthal found the solubility of potassium chromate, *S*, in the presence of *n*-normal soln. of various salts:

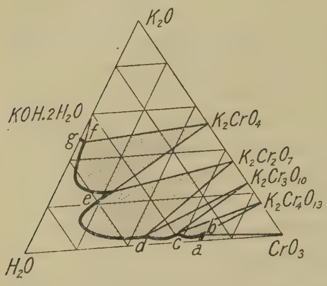

FIG. 36.—Equilibrium Diagram for the Ternary System: K_2O–CrO_3–H_2O at 30°.

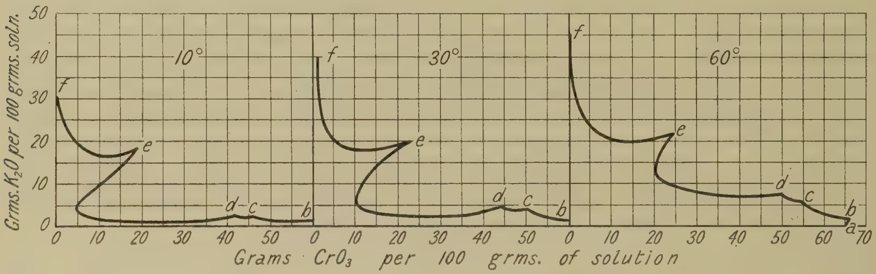

FIGS. 37, 38, and 39.—Solubility of Potassium Chromate in Solutions of Chromic Acid.

NaCl	*n* .	0	0·42	0·86	1·73	2·59	3·30	3·40	4·25
	S .	8·35	8·11	7·71	6·51	5·46	4·79	4·57	4·49
KCl	*n* .	0·40	0·46	1·31	1·72	2·18	2·70	—	—

KBr	*n* .	0·41	0·82	1·24	1·78	2·19	2·70	—	—
	S .	7·56	6·91	6·26	5·50	5·00	4·38	—	—
$MgCl_2$	*n* .	0·42	0·86	1·73	2·27	2·76	3·26	—	—
	S .	7·58	6·11	4·30	2·74	1·30	1·04	—	—
NH_4Cl	*n* .	0·45	0·83	1·81	2·34	2·73	3·76	4·51	—
	S .	7·68	6·92	5·58	5·00	4·43	3·49	2·87	—

for NaCl, $S=8·770-1·24n$; for KCl, $S=8·287-1·31n$; for KBr, $S=8·129-1·39n$; for $MgCl_2$, $S=8·697-2·68n$; and NH_4Cl, $S=8·318-1·425n$.

The rhombic, bipyramidal crystals are pseudohexagonal, and, according to E. Mitscherlich, have the axial ratios $a:b:c=0·5694:1:0·7298$. W. Brendler gave $a:b:c=0·5694:1:0·7298$ for crystals of tarapacaite. Observations on the crystals of potassium chromate were also made by H. J. Brooke, H. Baumhauer, H. Topsöe and C. Christiansen, F. Corio, W. J. Grailich and V. von Lang, F. Corio, A. Hettich and A. Schleede, etc. The habit was found by H. de Sénarmont to be tabular when the crystals are grown in a soln. of sodium carbonate; but J. W. Retgers said that the crystals are those of $K_3Na(CrO_4)_2$, and not of potassium chromate. R. Marc and W. Wenk found that the velocity of crystallization of fused potassium chromate is three-fourths the speed of that of fused potassium sulphate; O. Schott, that a soln. of the salt in molten potassium nitrate furnishes crystals with a habit different from that which later obtains; while O. Lehmann said that the habit of the crystals under these conditions is unchanged. The (010)- and (001)-cleavages are clear. O. Lehmann observed the development of cleavage planes as the solid is heated. K. Herrmann and co-workers found the X-radiograms of the rhombic bipyramidal crystals of potassium chromate have a simple lattice with four mols. per unit cell, with $a=7{\cdot}45$ A., $b=10{\cdot}3$ A.; and $c=5{\cdot}88$ A. E. Kochholm and N. Schönfeldt studied the isomorphism of this salt with potassium sulphate and selenate. H. Topsöe and C. Christiansen found that the optical character is negative, and the optic axial angle $2V=51°\ 40'$; and $2E=97°\ 30'$. W. J. Grailich and V. von Lang gave $2E=92°$. A. des Cloizeaux gave $2E=100°\ 32'$ for red-light, 95° 40′ for blue-light, and 93° 10′ for blue-light. H. de Sénarmont, and W. J. Grailich and V. von Lang found that the optic axial angles increase with a rise of temp. L. Stibing gave for the axial ratios of solid soln. of potassium sulphate and chromate with 0·5 molar per cent. of potassium chromate $a:b:c=0{\cdot}5727:1:0{\cdot}7434$; 0·19 per cent., 0·5723 : 1 : 0·7436; 2·44 per cent., 0·5719 : 1 : 0·7445; 8·26 per cent., 0·5715 : 1 : 0·7444; 38·47 per cent., 0·5712 : 1 : 0·7418; 90·59 per cent., 0·5704 : 1 : 0·7381; and 100 per cent. 0·5696 : 1 : 0·7351 when potassium sulphate alone has 0·5727 : 1 : 0·7418. The topic axes of potassium chromate are $\chi:\psi:\omega=3{\cdot}9708:4{\cdot}0113:5{\cdot}1244$, when those of potassium sulphate are 3·8576 : 3·8805 : 4·9968. E. Pietsch and co-workers studied the attack of the edges and corners of the crystals by sulphuric acid.

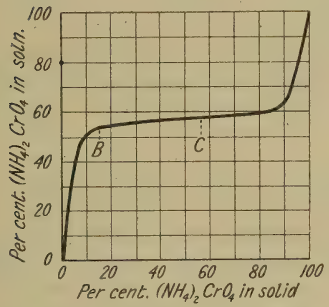

Fig. 40.—Solubility of the Binary System: $(NH_4)_2CrO_4$–K_2CrO_4 at 25°.

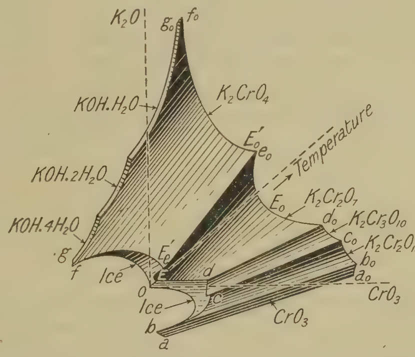

Fig. 41. — Equilibrium Model for the System: K_2O–CrO_3–H_2O at different Temperatures.

T. Ishikawa studied the system: $(NH_4)_2SO_4$–$(NH_4)_2CrO_4$–K_2CrO_4–K_2SO_4; and S. Araki found the solubility curves for the system $(NH_4)_2CrO_4$–K_2CrO_4–H_2O at 25°. The curve has two branches with two series of solid soln., and a gap with between 16·75 and 55·50 molar per cent. of ammonium chromate, *BC*, Fig. 40. According to S. F. Schemtschuschny, the cooling curve of potassium chromate exhibits two transition points, one at 984° corresponding with the crystallization of the molten liquid, and another at 679° corresponding with the conversion of the solid into another crystalline form, Fig. 42. This transition is attended by a change of the yellow into a red salt on heating. E. Groschuff said that this change of colour is evident at 260°, and that the change is gradual so that

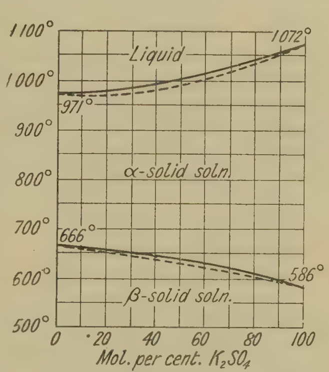

Fig. 42.—The Effect of Potassium Sulphate on the Freezing and Transition Points of Potassium Chromate.

it does not appear to be connected with the transition point. F. Rinne observed the reversibility of the colour changes when the salt is heated by the bunsen flame. E. Groschuff placed the transition temp. at 666°; and A. Hare, at 660°. The α-form is stable above 666°, and is completely miscible with the hexagonal form of potassium sulphate so that the high temp. form is itself hexagonal; as the ordinary or β-form of potassium chromate is completely miscible with the β-form of potassium sulphate. Neither the f.p. curve, nor the transition curves, Fig. 42, shows a maximum or minimum. M. Amadori obtained a similar equilibrium diagram. Yellow potassium chromate, stable at ordinary temp., is isomorphous with potassium sulphate, and, therefore, cannot be separated from that salt by fractional crystallization. W. von Behren and J. Traube studied the dissolution and crystallization of the salt. R. Kollmann, G. Tammann and A. Sworykin, E. Mitscherlich, P. Groth, C. F. Rammelsberg, and J. W. Retgers said the salt is isomorphous with potassium sulphate, selenate, and permanganate. G. Tammann discussed the protection of one salt by another in the case of solid soln. of potassium chromate and sulphate in a soln. of the sulphate. H. Rose observed that a mixture of eq. proportions of sodium sulphate and potassium chromate yields a brittle mass which dissolves in water and yields crystals resembling potassium sulphate. The optical properties of solid soln. of potassium sulphate and chromate were examined by L. Stibing, G. N. Wyrouboff, and E. Mallard; and the solubility and sp. gr. of soln. of the two salts were examined by M. Herz, A. Fock, and M. Amadori. G. Meyer studied the application of the partition law to the solid soln. of potassium sulphate and chromate in aq. soln. M. Amadori gave for the solubility of potassium chromate in the presence of the sulphate:

K_2SO_4	69·88	58·78	40·86	27·65	13·53	7·51	4·35	0
K_2CrO_4	0·00	22·44	75·34	140·7	266·5	315·7	324·5	332·3

so that the curve is in agreement with the results obtained by A. Fock, but not with those of M. Herz. The mutual solubility of the two salts in the solid state is complete; and the more soluble salt is always in greater proportion in the soln. than in the crystals. The solubility curve of potassium chromate and molybdate is similar. L. Stibing gave for mixtures of potassium sulphate and chromate in soln. and solid soln., when the composition is expressed in molar per cent. K_2CrO_4 per litre:

Soln.	0·0741	0·2642	0·6281	0·7543	1·0197	1·8450	2·6867
Solid	0·0053	0·02337	0·0294	0·0355	0·1603	0·1892	0·5795

A. Fock's results at 25° are summarized in Fig. 42. T. V. Barker studied parallel overgrowths on alkali sulphates and chromates. H. E. Buckley studied the effect of chromates on the crystallization of sodium chlorate.

T. Thomson gave 2·612 for the sp. gr. of potassium chromate; C. J. B. Karsten, 2·6402; H. Kopp, 2·705; L. Playfair and J. P. Joule, 2·711 to 2·72309 at 4°; S. Holker, 2·678 at 15·5°; H. Schiff, 2·691; F. Stolba, 2·7343; H. G. F. Schröder, 2·719 to 2·722; J. W. Retgers, 2·727; A. Cavazzi, 2·691 at 15°; B. Gossner, 2·741; J. L. Andreae, 2·7319 at 18°; and W. Spring,

	0°	10°	20°	40°	60°	80°	100°
Sp. gr.	2·740	2·737	2·735	2·729	2·723	2·711	2·7095

W. Spring, and L. Stibing observed the sp. gr. of solid soln. of potassium chromate and sulphate, and the values calculated by the additive rule:

K_2CrO_4	0·5080	1·2065	2·7093	9·3837	40·5333	91·5450 per cent.
Sp. gr. (Cals.)	2·6664	2·6669	2·6680	2·6732	2·6959	2·7345 ,,
Sp. gr. (Obs.)	2·666	2·667	2·668	2·673	2·696	2·735 ,,

F. Fouqué found that the sp. gr. of aq. soln. of potassium chromate with 0·97, 3·35, and 20·57 grms. of salt per 100 grms. of water are respectively 1·0077, 1·0268, and 1·1533 at 0°/4°; 1·0065, 1·0257, and 1·1500 at 16·4°/4°; 0·9836, 1·0013, and

1·1165 at 75·5°/4°; and 0·9679, 0·9861, and 1·1065 at 99°. Observations were also made by P. Kremers, R. L. Datta and N. R. Dhar, P. F. Gaehr, and A. Heydweiller. For soln. of the following percentage composition, at 195°, H. Schiff, and G. T. Gerlach found:

K_2CrO_4 .	1	5	10	15	20	25	30	35	40 per cent.
Sp. gr. .	1·0080	1·0492	1·0837	1·1287	1·1765	1·2274	1·2808	1·3386	1·3991

H. Schiff represented his results for soln. with p per cent. of K_2CrO_4 by $S=1+0·008p+0·0_43324p^2+0·0_64048p^3$ at 19·5°. F. Flöttmann found the sp. gr. of soln. sat. at 15°, 20°, and 25° to be, respectively, 1·3749, 1·3785, and 1·3805. A. Cavazzi measured the expansion in vol. which occurs when potassium chromate is dissolved in water. K. F. Slotte found the sp. gr. of a soln. with 24·26 per cent. K_2CrO_4 at 18° to be 1·2335; and the viscosity (water 100), 133·3 at 10°; 106·5 at 20°; 87·9 at 30°; and 74·3 at 40°. The drop weight of the salt just above its m.p. was found by I. Traube to be 238 mgrms. (water 100). J. Wagner found for N-, 0·5N-, 0·25N-, and 0·125N-soln. the viscosity (water unity) 1·1133, 1·0528, 1·0224, and 1·0116 respectively. L. J. Simon mixed equimolar soln. of chromic acid and potassium or sodium hydroxide, and found that discontinuities occur in the viscosity curves when the composition of the soln. corresponds with either the normal chromates or the dichromates, the precise form of the curves depending on whether the relative proportion of the two soln. is taken as the abscissa or the viscosities for soln. of equimolar conc. are compared. Except in high concentrations, the viscosities of eq. soln. of sodium chromate and sodium sulphate, and of potassium chromate and potassium sulphate are identical, and it is concluded that within certain conc. limits, isomorphous solutes produce the same change in the viscosity of the aq. solvent. T. Graham made some observations on the diffusion of potassium chromate into a soln. of potassium acetate; and J. C. G. de Marignac, on the diffusion in the presence of potassium carbonate, or nitrate. Experiments on the diffusion of soln. of chromic acid were also made by F. Rudorff, and H. de Vries. G. Jander and A. Winkel gave 0·77 for the diffusion coeff. of the anion. W. Spring found that with the vol. of potassium chromate unity at 0°, the vol., v, at different temp. is:

	10°	20°	30°	40°	60°	80°	100°
v .	1·001064	1·002114	1·003140	1·004228	1·006439	1·009023	1·011344

which makes the coeff. of cubical expansion 0·00011344 between 0° and 100°, a result very close to that obtained by L. Playfair and J. P. Joule; J. L. Andreae gave 0·000101 between 18° and 56°. W. Spring also found that the coeff. of cubical expansion is very close to that of ammonium and rubidium sulphates. H. Kopp observed the sp. ht. of the crystalline salt to be 0·189 between 18° and 47°; H. V. Regnault gave 0·1850 between 17° and 98°; and F. E. Neumann, 0·1840. J. C. G. de Marignac gave for the sp. ht. of soln. of a mol of potassium chromate in 50, 100, and 200 mols of water between 20° and 51°, respectively 0·8105, 0·8896, and 0·9407; while H. Faasch gave for 0·499N-, 0·990N-, 1·994N-, and 3·986N-K_2CrO_4, respectively 0·939, 0·898, 0·810, and 0·703 at 18°. The subject was discussed by N. de Kolossowsky. J. J. Berzelius observed that the lemon-yellow salt becomes bright red when heated, but undergoes no further change; it is liable to decrepitate violently before fusion at a red-heat, and emits a green light during fusion; and the molten salt, said G. Magnus, crystallizes as it cools. H. le Chatelier first gave 975° for the m.p., and later,

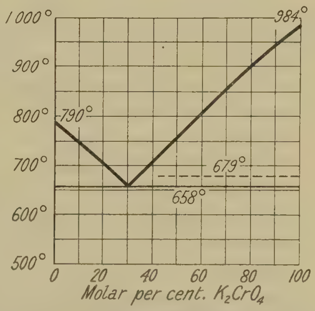

FIG. 43.—Freezing-point Curve of the Mixtures of K_2CrO_4–K_2SO_4.

940°; S. F. Schemtschuschny, 984°; E. Groschoff, 971°; and M. Amadori, 978°. D. F. Smith and F. A. Hartgen studied this subject. For the transition temp., *vide supra.* H. le Chatelier, E. Groschuff, and M. Amadori studied the m.p. of mixtures of potassium sulphate and chromate—*vide* Fig. 43—a continuous series of solid soln. is formed. M. Amadori obtained continuous series of solid soln. with potassium chromate and potassium molybdate or tungstate. S. F. Schemtschuschny studied the m.p. of the binary system K_2CrO_4–KCl, and found a typical V-curve with a eutectic at 658°, and 31·5 molar per cent. of K_2CrO_4; no solid soln. are formed on the potassium chloride branch of the curve, but the other branch shows that solid soln. are formed with mixtures containing about 4 molar per cent. of potassium chloride, Fig. 43. F. Guthrie found that a mixture of potassium chromate and nitrate has a eutectic at 295° and 96·2 per cent. of the nitrate; for mixtures of potassium chromate and dichromate, *vide infra.* The lowering of the f.p. of soln. of w grms. of K_2CrO_4 in 100 grms. of water, was measured by L. C. de Coppet, and F. Rüdorff; while I. Koppel and E. Blumenthal gave:

K_2CrO_4 .	4·53	6·12	26·99	31·33	42·04	54·57
Lowering f.p.	0·99°	1·2°	4·3°	5·7°	7·12°	11·37°

For the eutectic temp., *vide supra.* G. Tammann gave for the lowering of the vap. press. for soln. with w grms. of K_2CrO_4 per 100 grms. of water,

K_2CrO_4 . . .	10·93	14·29	26·63	34·89	46·99	53·28
Lowering v.p. .	18·0	22·7	40·4	52·1	73·7	84·1 mm.

I. Bencowitz and H. T. Hotchkiss, and F. M. Raoult made some observations on this subject. According to M. Alluard, the b.p. of a sat. soln. of the chromate is 104·2° at 718 mm.; according to P. Kremers, 107°; and according to I. Koppel and E. Blumenthal, 105·8° at 760 mm. A. Hare found the heat of the polymorphic transformation of potassium chromate at 660° to be 2·45 Cals. per mol. R. Lorenz and W. Herz studied some relations between the b.p. and critical temp. The heats of neutralization given by M. Berthelot are $(CrO_{3aq.},2KOH_{aq.})=30·4$ Cals. at 12°; with the solid compounds, 95·6 Cals.; with $K_2Cr_2O_7$ (in 12 litres) and 2KOH (in 4 litres), M. Berthelot gave 23·6 Cals., and P. Sabatier, 23·0 Cals.; and for H_2CrO_4 (in 8 litres) and 2KOH (in 4 litres). M. Berthelot gave 27·738 Cals., and P. Sabatier, 25·4 Cals. M. Berthelot also gave for $(2Cr(OH)_{3\text{precipitated}},4KOH_{aq.},3O)=61·4$ Cals. at 8°; and for solid hydroxide and chromate, 101·9 Cals. F. Morges gave −5·254 Cals. for the heat of soln. in 543 mols of water at 19·5°.

H. Topsöe and C. Christiansen gave for the index of refraction, 1·7131 for the *C*-line; 1·7154 for the *D*-line; and 1·7703 for the *F*-line. E. Mallard gave for red-light, $\alpha=1·6873$, $\beta=1·722$, and $\gamma=1·7305$. F. Fouqué, and R. L. Datta and N. R. Dhar measured the refractive indices of aq. soln.; and A. Heydweiller gave for the *D*-line at 18°:

K_2CrO_4 . .	0·1*N*-	0·2*N*-	0·5*N*-	1·0*N*-	2·0*N*-	4·0*N*-
μ . . .	1·33529	1·33732	1·34335	1·35305	1·37188	1·40709

F. Flöttmann found the index of refraction of soln. sat. at 15°, 20°, and 25° to be respectively 1·43267, 1·43276, and 1·43288. H. Fromherz studied the absorption spectrum. L. R. Ingersoll found Verdet's constant for the electromagnetic rotatory power for light of wave-length 0·6, 0·8, 1·0, and 1·25μ to be respectively 0·0092, 0·0060, 0·0041, and 0·0026 for soln. of sp. gr. 1·372. T. Thomson said that one part of the salt imparts a distinct yellow colour to 40,000 parts of water. The spectroscopic observations of H. Becquerel, W. Böhlendorff, A. Étard, F. Grunbaum, J. M. Hiebendaal, J. H. Jones and W. W. Strong, E. Viterbi and G. Krausz, O. Knoblauch, P. Sabatier, J. L. Soret, H. Settegast, A. M. Taylor, T. Aden, N. R. Tawde and E. R. Paranjpe, E. Jander, and K. Vierordt have been previously discussed. C. Schaefer and M. Schubert found in the ultra-red spectrum a well-defined maximum at 11·16μ with soln. of potassium chromate, and at 11·2μ with soln. of potassium sodium chromate. H. von Halban and K. Siedentopf studied the absorption of light in cells of potassium chromate and hydroxide soln., and soln. of potassium chromate and copper sulphate in aq. ammonia. A. E. Lindh, D. Coster, and O. Stelling studied the X-ray spectrum; and D. M. Yost, the absorption of X-rays. I. Plotnikoff and M. Karshulin measured the absorption spectrum and the region of photochemical sensitivity for soln. of potassium chromate in colloidion films—with methyl alcohol as acceptor. A. Kailan found that an aq. soln. of potassium chromate is reduced by radium rays more slowly than potassium dichromate. E. Montignie observed that after exposure to ultra-violet light, potassium chromate affects a photographic plate.

J. A. Fleming and J. Dewar found that the dielectric constant of water is raised a little by potassium chromate, and at —88·5°, the dielectric constant of the frozen mixture is between 3 and 10—when with ice alone, the constant is 2·5. W. Schneider studied the piezoelectric effect; P. Walden, and A. Heydweiller, the electrical conductivity of aq. soln. P. Walden gave for the eq. conductivity, λ mhos, at 8°, with a gram-equivalent of the salt in v litres,

v . . .	32	64	128	256	512	1024
λ . . .	129·6	136·3	141·3	145·5	148·3	150·4

H. C. Jones and C. A. Jacobson measured the molar conductivity, μ mhos, between 0° and 35°, and A. M. Clover and H. C. Jones, between 35° and 65°, for a mol of the salt in v litres; and calculated values for the percentage ionization, α;

v	. .	2	8	16	32	128	512	1024	2048
μ	0° . .	102·9	118·6	125·6	132·8	149·3	156·8	160	161·4
	125° .	136·6	161·9	174·3	185·2	204	219	223	225
	25° .	176·6	209	228	242	270	290	294	298
	35° .	211	251	273	290	323	349	352	356
	50° .	266	317	—	366	415	442	—	—
	65° .	316	381	—	445	429	548	—	—
α	0° .	63·7	73·5	77·8	82·5	92·5	97·2	99·1	100·0
	35° .	59·6	70·4	76·6	81·4	90·6	98·1	98·8	100·0

Conductivity observations were also made by R. Lenz, and E. Bouty. N. R. Dhar said that electrical conductivity and coagulation experiments agree that in soln. the dichromate is in part present as $KHCrO_4$. F. Morges observed that in the electrolysis of an aq. soln. of the chromate, potassium hydroxide accumulates about the cathode, and the oxygen given off at the anode forms dichromate—*vide supra*. chromic acid. As indicated in connection with chromic acid, calculations on the degree of ionization are unsatisfactory on account of the conversion of chromates to dichromates in aq. soln. J. Lundberg's observations on the hydrolysis of these soln. were indicated in connection with chromic acid. The aq. soln. has an alkaline reaction towards lacmoid, litmus, and phenolphthalein, and observations on this subject were made by M. M. Richter, R. T. Thomson, and J. A. Wilson. H. M. Vernon estimated the degree of ionization from the colour. G. Baborovsky studied the electrolytic reduction of the salt; and P. Düllberg, the electrometric titration with hydrochloric acid. L. A. Welo gave $0{\cdot}04\times10^{-6}$ for the magnetic susceptibility. G. Gore electrolyzed fused potassium chromate and obtained a deposit on the cathode.

J. Obermiller measured the hygroscoposity of the crystals. H. Moser said that potassium chromate is not decomposed when heated to redness—*vide supra*, chromium trioxide. W. Ipatieff and co-workers found that hydrogen under a press. of 200 atm. reduces soln. of potassium chromate; and with a soln. of potassium chromate and sulphuric acid, $Cr_2(SO_4)_3.Cr_2O_3.K_2O.H_2O$ is formed. G. Gore observed that the salt becomes red in compressed hydrogen chloride, but in liquid hydrogen chloride it is neither changed nor dissolved. A. C. Robertson studied the action of potassium chromate on hydrogen dioxide: $2K_2CrO_4+H_2O_2=K_2Cr_2O_7$

$+2KOH+O$—*vide supra,* potassium dichromate; and *vide supra,* chromic acid. G. Grasser and T. Nagahama found that the reduction with many reducing agents is incomplete unless an acid be present. J. W. Thomas found that the salt is decomposed by dry hydrogen chloride forming potassium chloride and dichromate; the dichromate is then converted into chromium trioxide, and this is then reduced to a brown chromic oxide without forming chromyl chloride. M. Bobtelsky studied the oxidation of conc. hydrochloric acid by potassium chromate. W. B. Morehouse found the X-ray absorption of the system: $K_2Cr_2O_7+16KI+14HCl \rightarrow 8KCl +2CrCl_3+4I_2+8KI+7H_2O$ is 0·25 per cent. greater after the reaction than it is before. E. Ramann and H. Sallinger measured the precipitation ratio, *i.e.* the ratio in which silver divides itself between the iodate and chromate in the reaction: $K_2CrO_4+2AgIO_3=2KIO_3+Ag_2CrO_4$. J. L. Lasssaigne found that when heated with sulphur, chromic oxide and potassium sulphate and sulphide are formed: $8K_2CrO_4+(3n+5)S=5K_2SO_4+3K_2S_n+4Cr_2O_3$; initially, said O. Döpping, some thiosulphate is produced. K. Brückner said that when the mixture of chromate and sulphur is heated for a short time, potassium sulphide and thiosulphate are formed, and afterwards potassium sulphate and polysulphide as well as chromic sulphide and oxide. As the heating continues, the sulphide is slowly oxidized, and the end-products are potassium sulphate, and chromic oxide with traces of chromates, and chromium sulphide. J. B. Senderens represented the reaction when the aq. soln. is boiled with sulphur, by $6K_2CrO_4+15S+9H_2O=6Cr(OH)_3 +5K_2S_2O_3+K_2S_5$; and O. Döpping, the reaction with potassium pentasulphide, by $8K_2CrO_4+2K_2S_5+5H_2O=5K_2S_2O_3+10KOH+4Cr_2O_3$. The reaction between the heated salt and dry hydrogen sulphide was found by W. Müller to furnish water, potassium and chromium sulphides and chromic oxide; with an aq. soln. of the chromate, saturated with sodium hydroxide, T. L. Phipson found that green chromic hydroxide is precipitated—*vide infra;* chromium sulphide. W. R. Hodgkinson and J. Young studied the action of dry sulphur dioxide on the salt. W. Müller represented the reaction between the heated salt and the vapour of carbon disulphide by $2K_2CrO_4+5CS_2=2K_2S_3+Cr_2S_3+4CO+CO_2+SO_2$. P. Berthier said that sulphur dioxide precipitates brown chromic chromate from an aq. soln. of potassium chromate. The precipitate then dissolves forming a green liquid containing potassium hydroxide, chromic oxide and sulphuric, sulphurous, and dithionic acids. P. Job found that 0·01 to $0{\cdot}001M$-K_2CrO_4, reacts with sulphuric acid, so that the reaction $CrO_4''+H^{\cdot}\rightleftharpoons HCrO_4'$ has an ionization constant $K=7\times10^{-5}$ at 15°. E. Pietsch and co-workers studied the surface conditions in the reaction between potassium chromate and sulphuric acid. E. C. Franklin and C. A. Kraus found the chromate to be insoluble in liquid ammonia. H. Stamm found that soln. with 0, 1·350, and 3·517 grms. of NH_3 per 100 grms. of water dissolve 0·3218, 0·0324, and 0·0036 mol of K_2CrO_4 respectively. R. C. Woodcock, and F. Mohr found that when the chromate is distilled with ammonium chloride and water, ammonia and potassium dichromate are formed. F. Santi found that ammonium chloride converts chromates to dichromates and dichromates to chromic acid; and E. Divers that chromates react with a soln. of ammonium nitrate in aq. ammonia. H. P. Cady and R. Taft observed that potassium chromate is appreciably soluble in phosphoryl chloride. J. T. Cooper observed that a yellow soln. of chromate gradually turns green in the presence of arsenic trioxide. H. Moser observed the decomposition of potassium chromate mixed with carbon and heated—potassium carbonate and chromic oxide are formed. E. Fleischer observed that the aq. soln. of the chromate attracts carbon dioxide from the atm. When the chromate is heated in a current of carbon monoxide, F. Göbel observed that chromic oxide is formed; and K. Stammer added that potassium carbonate, carbon dioxide, and potassium chromite are also produced. J. Jacobson found that when carbon, gun cotton, and other organic substances are soaked in a soln. of potassium chromate and dried, they burn more vigorously than before. F. W. O. de Coninck observed that 100 grms. of a soln. of glycol sat. at 15·4, contain 1·7 grms. of potassium chromate. A. Naumann found the chromate to be insoluble in benzonitrile, and in methyl acetate; and A. Naumann, and W. Eidmann, insoluble in acetone. It is also insoluble in alcohol. F. Göbel found that potassium chromate is partially decomposed when heated in carbon monoxide, and chromic oxide is formed. G. Stadnikoff studied the adsorption of potassium chromate by aniline-black. S. Glasstone and co-workers studied the effect of the chromate on the solubility of ethyl alcohol. F. Tassaert observed that when the chromate is heated with acetic acid and alcohol, it is partly transformed into potassium and chromic acetates. According to F. Tassaert, many acids—sulphuric, hydrochloric, nitric, and acetic acids—abstract half the alkali, and form potassium dichromate, which, if the soln. be sufficiently concentrated, is precipitated—*vide supra*, chromium trioxide. E. Schweizer said that carbonic acid acts similarly, and F. Margueritte, boric acid; but F. Mohr added that boric and silicic acids, and potassium hydrocarbonate do not act in this way, but that formic, acetic, butyric, and valerianic acids do transform chromate into dichromate. If soln. of the potassium salts of one of these four acids be evaporated with potassium dichromate, potassium chromate is formed. F. Mohr added that potassium hydrocarbonate acts similarly. According to E. Schweizer, a soln. of potassium dichromate with sodium stearate precipitates stearic acid; benzoic acid forms potassium benzoate and dichromate when treated with potassium chromate, and when the soln. is evaporated, potassium chromate and benzoic acid are reformed. A soln. of sodium benzoate and potassium dichromate does not yield chromate on evaporation. Salicylic acid behaves like benzoic acid. Normal potassium urate reacts with the chromate forming uric acid and potassium dichromate. M. Berthelot, and P. Sabatier studied the reaction of the chromate with acids. According to J. W. Döbereiner, a soln. of barium hydroxide gives a quantitative precipitate of barium chromate. According to L. Meyer, an aq. soln. of potassium chromate in contact with crystals of copper sulphate, silver nitrate, mercurous nitrate, or mercuric chloride forms potassium dichromate and a little basic chromate is precipitated; lead acetate is not changed; cobaltous chloride gives a precipitate—*vide supra*, reactions of chromates. K. W. Floroff studied the reaction $BaSO_4+K_2CrO_4=K_2SO_4+BaCrO_4$. L. Kahlenberg and W. J. Trautmann observed no reaction when the chromate mixed with silicon is heated in a hard glass tube by a bunsen burner, but there is a strong reaction when heated by a méker burner. A. C. Robertson represented the reaction with vanadic acid: $2K_2CrO_4+H_2O_2+HVO_3=K_2Cr_2O_7+2KOH+HVO_4$. R. F. Reed and S. C. Horning showed that potassium chromate in aq. soln. is absorbed by zinc, possibly as potassium or zinc chromate.

S. W. Johnson cooled by a freezing mixture a hot soln. of potassium dichromate in conc. ammonia, and obtained crystals of **ammonium potassium chromate,** $(NH_4)KCrO_4$; E. Kopp obtained the same salt by evaporating the soln. over caustic alkali. The rhombic, pale sulphur-yellow prisms are isomorphous with potassium sulphate. E. Maumené said that the salt turns brown at 240° owing to the formation of the chromate of a base N_2H_6O, and that the salt is completely decomposed at 270° leaving residual chromic oxide. P. Sabatier gave 10·6 Cals. for the heat of formation from a soln. of potassium dichromate; or 15·5 Cals. from the solid salts; the heat of soln. for 173·4 grms. of salt in 40 times its weight of water at 17° is $-5·3$ Cals. S. W. Johnson found that the salt loses ammonia when exposed to air, and when the soln. is boiled or evaporated there remains potassium dichromate. E. Kopp said that sodium thiosulphate has no action in the cold, but when heated, chromic chromate is formed. A. Étard's analysis indicates that the salt is monohydrated; but S. W. Johnson's analysis shows that the salt is anhydrous. J. Zehenter prepared $2(NH_4)_2CrO_4.3K_2CrO_4$, by adding an eq. of potassium carbonate to a conc. soln. of ammonium dichromate, and precipitating with alcohol. The sulphur-yellow needles have a sp. gr. 2·403 at 15°. They are stable when dry. H. Traube prepared **lithium potassium chromate,** $LiKCrO_4$, in hexagonal or pseudo-hexagonal crystals isomorphous with the analogous sulphate; J. Zehenter gave 2·539 for the sp. gr. at 15°. H. Rose melted 2 parts of potassium dichromate and one of sodium carbonate; the cold mass dissolved in hot water deposits, on cooling, crystals of **potassium sodium chromate,** or *chromoglaserite,* or *chromatoglaserite,* $3K_2CrO_4.Na_2CrO_4$, or $K_3Na(CrO_4)_2$—the crystallization is attended by crystalloluminesce. J. Zehenter obtained the salt by evaporating a hot soln. of potassium dichromate neutralized with sodium carbonate; and C. von Hauer, by evaporating a mixed soln. of 3 mols of potassium chromate and one mol of sodium chromate. The yellow crystals were found by B. Gossner to be trigonal with the axial ratio $a:c=1:1{\cdot}2857$ and $\alpha=88°\ 28'$, there is a second variety in monoclinic crystals with $a:b:c=0{\cdot}5833:1:0{\cdot}8923$, and $\beta=90°\ 46'$. H. Steinmetz said that there is a gradual change in the chromate, $K_3Na(CrO_4)_2$, between 150° and 175° without appreciable change of vol. or coeff. of expansion. The sp. gr. is 2·719 at 15°; at 14°, 100 parts of water dissolve 64·2 parts of salt. According to J. Zehenter, the mother-liquor yields a hemihydrate, of sp. gr. 2·575 at 15°. It loses water at 150°; and 100 parts of water at 14° dissolve 66·4 parts of salt. E. Flach measured the f.p. of mixtures of sodium and potassium chromates, and the results are summarized in the upper curve of Fig. 44. The solid soln. of the two salts shows breaks in the cooling curve corresponding with the lower curve of Fig. 44. There are thus indications of the formation of the trigonal chromatoglaserite analogous to ordinary or sulphatoglaserite, $3K_2SO_4.Na_2SO_4$. This complex salt can form solid soln. to a limited extent with sodium chromate, so that during the cooling the hexagonal crystals of the solid soln. between 669° and 371° mostly split into simple chromates and solid soln. of chromatoglaserite and sodium chromate. The curve of mixtures of potassium and sodium chromates, previously fused together, shows a break corresponding with $K_3Na(CrO_4)_2$. Thus,

K_2CrO_4 .	0	10	50	70	78·3	90	100 per cent.

L. Grandeau [5] prepared **rubidium chromate,** Rb_2CrO_4, by neutralizing a soln. of the dichromate with rubidium carbonate, and by melting chromic oxide with rubidium nitrate, or with rubidium carbonate in air. The spontaneous evaporation of the aq. soln. furnishes first a crop of crystals of the dichromate, and then the chromate. The aq. soln. has an alkaline reaction. According to J. Piccard, the yellow crystals are rhombic bipyramids with the axial ratios $a : b : c = 0{\cdot}5665 : 1 : 0{\cdot}7490$. The (001)-cleavage is marked. The optic axial angles found by G. N. Wyrouboff were $2H_0 = 73° 46'$ for red-light, and 76° 5′ for green-light; and $2H_0 = 146°$ for white light. The topical character is negative. J. W. Retgers, J. Piccard, and L. Grandeau said that the crystals are isomorphous with potassium chromate, sulphate, and selenate. T. V. Barker studied parallel overgrowths on alkali sulphates and chromates. F. A. H. Schreinemakers and H. Filippo found the percentage solubility, S, to be:

	−7°	0°	10·3°	20°
S .	36·6	38·2	40·2	42·4

	30°	40°	50°	60·4°
S .	44·1	46·1	47·4	48·9

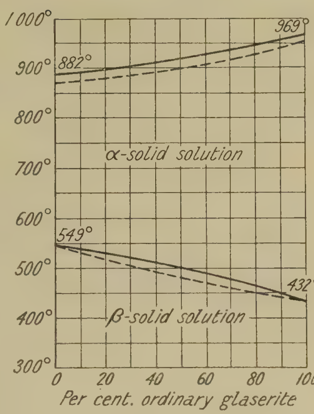

FIG. 45.—The Binary System of Sulphato- and Chromato-glaserites.

They also studied the ternary system: Rb_2O–CrO_3–H_2O at 30°; and found that with the composition of the soln. expressed in percentages:

CrO_3 . .	0	0·00	11·98	15·54	4·87	15·05
Rb_2O . .	60·56	56·82	27·99	28·55	4·60	3·45
Solids	$RbOH.2H_2O$	Rb_2CrO_4		$Rb_2Cr_2O_7$		

CrO_3 . .	15·05	24·92	14·29	58·69	63·07	62·28
Rb_2O . .	3·45	1·66	1·28	1·07	0·92	0
Solids	$Rb_2Cr_3O_{10}$		$Rb_2Cr_4O_{13}$		CrO_3	

The results are plotted in Fig. 46; where the solubility curve *ab* refers to the solid phase CrO_3; *bc*, to $Rb_2Cr_4O_{13}$; *cd*, to $Rb_2Cr_3O_{10}$; *de*, to $Rb_2Cr_2O_7$; *ef*, to Rb_2CrO_4; and *fg*, to $RbOH.nH_2O$.

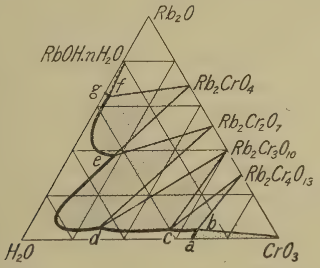

FIG. 46.—Equilibrium Diagram for the Ternary System: Rb_2O–CrO_3–H_2O.

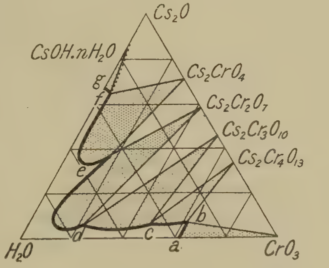

FIG. 47.—Equilibrium Diagram for the Ternary System: Cs_2O–CrO_3–H_2O at 30°.

C. Chabrié[6] obtained **cæsium chromate,** Cs_2CrO_4, by treating silver chromate with a boiling soln. of cæsium chloride, and evaporating the filtrate for crystallization; or more simply from an aq. soln. of chromic acid and cæsium carbonate. According to F. R. Fraprie, the crystals exist in two forms. C. Chabrié's process furnishes the so-called α-crystals in pale yellow, trigonal prisms with the axial ratio $a : c = 1 : 1{\cdot}2314$; while the β-crystals form dark yellow, rhombic bipyramidal crystals with the axial ratios $a : b : c = 0{\cdot}5640 : 1 : 0{\cdot}7577$, and which show twinning about the (130)-plane. These crystals are completely isomorphous with the potassium chromate family—a subject also discussed by J. W. Retgers. T. V. Barker studied parallel overgrowths on alkali sulphates and chromates. F. A. H. Schreinemakers and D. J. Meijeringh observed that in the ternary system: Cs_2O–CrO_3–H_2O at 30°, the composition of the soln. expressed in percentages, is:

CrO_3 .	0	0·119	9·662	13·08	8·98	2·16	4·57
Cs_2O .	70·63	69·22	31·68	35·08	24·05	3·04	1·61
Solids.	$CsOH.nH_2O$		Cs_2CrO_4		$Cs_2Cr_2O_7$		

CrO_3 .	4·57	25·59	44·45	55·17	62·70	62·50	62·28
Cs_2O .	1·61	0·096	3·13	3·90	4·35	2·33	0
Solids.		$Cs_2Cr_3O_{10}$		$Cs_2Cr_4O_{13}$		CrO_3	

The line *ab*, Fig. 47, is the solubility curve with CrO_3 as solid phase; *bc*, with $Cs_2Cr_4O_{13}$; *cd*, with $Cs_2Cr_3O_{10}$; *de*, with $Cs_2Cr_2O_7$; *ef*, with Cs_2CrO_4; and *fg*, with $CsOH.nH_2O$. The sodium and ammonium salts are alone hydrated in the ternary systems at 30° and the solubilities of the different alkali chromates at 30° are:

	Li	Na	NH_4	K	Rb	Cs
M_2CrO_4 .	49·98	46·63	28·80	39·63	44·14	47·0

M. Rosenfeld[7] obtained a green precipitate on adding a soln. of cuprous chloride in a conc. soln. of sodium chloride to an excess of a soln. of potassium chromate. The reaction was studied by H. J. P. Venn and V. Edge. Complex precipitates are formed differing in colour and constitution according to the method of preparation. The reaction consists essentially in the oxidation of the cuprous salt, and the formation of basic compounds whose composition changes when they are washed. The ultimate reactions are represented by: $3Cu_2Cl_2+2K_2CrO_4+8H_2O=4KCl+CuCl_2+5Cu(OH)_2+2Cr(OH)_3$, and $3Cu_2Cl_2+K_2Cr_2O_7+7H_2O=2KCl+2CuCl_2+4Cu(OH)_2+2Cr(OH)_3$. Intermediate products are represented by $2CuO.CuCl_2.3H_2O$, and $3CuO.CuCl_2.4H_2O$. J. Schulze reported normal **copper chromate,** $CuCrO_4$, to be formed when copper hydroxide is heated with an excess of a soln. of potassium dichromate in a sealed tube at 220°. Under ordinary conditions, J. Schulze, and M. Prud'homme and F. Binder found that a boiling soln. of the dichromate and copper hydroxide forms a basic chromate. According to G. Brügelmann, and J. C. G. de Marignac, the spontaneous evaporation of an aq. mixture of sat. soln. of copper sulphate and potassium dichromate gives first a crop of crystals of potassium sulphate, and then mixed crystals of chromates of indefinite composition. G. Quincke studied the formation of copper chromate by the diffusion of a soln. of copper sulphate into gelatine containing sodium dichromate. S. H. C. Briggs obtained normal copper chromate from a soln. of 3 grms. of copper carbonate with 6·9 per cent. CuO in 2·4 grms. of chromium trioxide dissolved in 20 c.c. of water, and, when the evolution of carbon dioxide has ceased, heated in a sealed tube for 2 or 3 hrs. at 200°; and also by boiling, in a vessel fitted with a reflux condenser, a mixture of 12 grms. copper carbonate, 21 grms. chromium trioxide, and 15 c.c. of water over an oil-bath; the product was washed with water and dried in a desiccator. H. Kopp, and G. C. Gmelin obtained crystals of copper chromate, isomorphous with pentahydrated copper sulphate, from a soln. of copper hydroxide in aq. chromic acid. M. Prud'homme said that if a soln. of chromic and cupric oxides in alkali-lye be allowed to stand some months, it deposits crystals of cupric chromate. H. W. Morse studied the rhythmic precipitation of the chromate.

J. Schulze said that the crystals are iron-black or reddish-brown with the appearance of hæmatite; the salt forms copper chromite at 400°. L. and P. Wöhler found that decomposition begins at 325°; at 340°, the partial press. of the oxygen is 417 mm.; and at 380°, over 750 mm. No state of equilibrium was observed. At 650°, cuprous chromite is formed. J. Schulze said that cupric chromate is insoluble in water, but it is soluble in acids including chromic acid. The salt is hydrolyzed by boiling water, leaving a basic chromate—possibly $3CuO.CrO_3.2H_2O$—as a residue. S. H. C. Briggs said that cupric chromate is not soluble in a soln. of copper sulphate.

According to M. C. Schuyten, when an aq. soln. of copper sulphate and potassium dichromate is treated with ammonia, or if potassium dichromate be added to an ammoniacal soln. of cupric hydroxide from which the excess of ammonia has been removed by exposure to air, **copper tetratotriamminochromate,** $4CuCrO_4.3NH_3.5H_2O$, separates as a brown, amorphous powder; when heated, it evolves ammonia, water, and a small quantity of nitrous fumes, but the whole of the ammonia and water cannot be expelled even by heating for a long time at a high temp. It dissolves in hydrochloric acid or ammonia, forming a yellow or a green soln. respectively; it is also easily soluble in a soln. of silver nitrate, but insoluble in organic solvents. Alcohol is not oxidized to aldehyde by boiling with the hydrochloric acid soln. of this compound. S. H. C. Briggs obtained **copper hemiheptamminochromate,** $2CuCrO_4.7NH_3.H_2O$, by pouring an aq. soln. of 14 grms. of copper carbonate and 25 grms. of chromium trioxide into a mixture of 125 c.c. conc. aq. ammonia, 50 c.c. of water, and 15 grms. of potassium hydroxide and allowing it to stand exposed to air. The greenish-black crystals lose ammonia at ordinary temp.; they are decomposed by water; and are soluble in dil. aq. ammonia. N. Parravano and A. Pasta prepared **copper tetramminochromate,** $CuCrO_4.4NH_3$, by adding alcohol to a soln. of copper tetrapyradinochloride in aq. ammonia; the green prismatic crystals are decomposed by water.

L. N. Vauquelin said that when potassium "chromate" is added to a soln. of a neutral copper salt, a chestnut-brown precipitate is produced, which, according C. Gerhardt, and C. Freese, consists of $K_2O.3CuO.3CrO_3.2H_2O$, or, according to M. Gröger, $KCu_2(OH)(CrO_4)_2.H_2O$, and which, according to G. C. Gmelin, furnishes potassium dichromate when treated with boiling water. A. Bensch noticed that when potassium chromate is added to a boiling, aq. soln. of copper sulphate, the blue colour changes from green to yellow to red, and then a brown precipitate forms. B. Skormin obtained **copper trioxychromate,** $3CuO.CuCrO_4.3H_2O$, by the action of an alkaline soln. of an excess of potassium chromate on a soln. of copper sulphate. F. J. Malaguti and M. Sarzeau said that after repeated extraction with boiling water, there remains—according to the analyses of F. J. Malaguti and M. Sarzeau, J. Persoz, C. Freese, J. Schulze, L. Balbiano, M. Gröger, and M. Rosenfeld—**copper dioxychromate,** $3CuO.CrO_3.2H_2O$, or $2Cu(OH)_2.CuCrO_4$; and, added M. Gröger, the same product is obtained whether the potassium chromate or the copper salt be in excess. This salt was also prepared by B. Skormin. According to M. Rosenfeld, this compound is formed when potassium chromate is added to a soln. of copper sulphate; although the colour of the substance varies with the temp. and conc. of the soln. its composition is constant. The same salt is formed by digesting freshly precipitated copper hydroxide with a soln. of potassium dichromate, but in this case it is mixed with crystals of potassium dichromate. M. Gröger said that the amorphous rust-brown precipitate, obtained by mixing aq. soln. of copper sulphate and potassium chromate, becomes crystalline when left in contact with excess of the copper salt soln. The precipitate is basic potassium cupric sulphatochromate, the proportion of sulphate present depending on the conc. of the copper salt soln. and the duration of its contact with the precipitate. The double salt is rapidly decomposed either by boiling water or by fusion, but without forming potassium chromate. The same precipitate is obtained on adding potassium hydroxide to the mixture of cupric sulphate and potassium dichromate in aq. soln. as indicated by A. Knopp. M. Gröger also said that the addition of sodium chromate to an aq. soln. of copper chloride results in the formation of a greenish-yellow precipitate which, when left in the mother-liquor, gradually assumes a bright rusty-brown colour, but does not become crystalline. The greenish-yellow substance is the basic cupric chromate, $2Cu(OH)_2,CuCrO_4$; the rusty-brown precipitate contains a larger proportion of chromic acid, which is removed by washing with water, the greenish-yellow salt being regenerated. According to L. Balbiano, a soln. of cupric sulphate is not completely precipitated by neutral ammonium chromate, the complete precipitation only being effected by the addition of ammonia.

Both the precipitate first produced by the ammonium chromate and that by the later addition of the ammonia have the same composition, $2CuO.CuCrO_4.2H_2O$. If the aq. soln. be evaporated on the water-bath, an amorphous mass is formed. Alcohol precipitates from the aq. soln. a dirty green precipitate, and is at the same time oxidized to acetic acid. In repeating L. Balbiano's experiments, M. Gröger observed that the original precipitate contains ammonium, and this salt furnishes the basic salt, $2Cu(OH)_2.CuCrO_4$, by washing with boiling water. A. Viefhaus obtained the same basic salt by digesting barium chromate with an aq. soln. of copper sulphate for 3 days at 30° to 35°; C. Freese, and M. Rosenfeld, by treating copper oxide or hydroxide with a boiling soln. of potassium dichromate, and extracting the product with boiling water; C. Freese, and R. Böttger, similarly treated copper carbonate with an aq. soln. of chromic acid. J. Schulze obtained this basic salt by the action of boiling water on copper chromate; and F. Dröge, by the action of boiling water on copper decamminodioxychromate. The dark brown flocculent precipitate dries at 100° to a dark brown, almost black, amorphous powder. J. Persoz said that it loses no water at 170°, but decomposes at a red-heat. F. J. Malaguti and M. Sarzeau said that it is soluble in dil. nitric acid, and in aq. ammonia. G. Gore observed that it is insoluble in liquid ammonia; R. Böttger, that it is decomposed by alkali-lye forming copper oxide; J. W. Slater, that when boiled with phosphorus, it forms copper, copper phosphide and phosphate, chromic phosphate, and phosphorus and phosphoric acids. R. Otto recommended its use in the determination of sulphur in organic analyses.

According to H. Moser, potassium dichromate does not give a precipitate with an aq. soln. of a copper salt; but, added W. E. Garrigues, if an excess of ammonia or, according to A. Kopp, and M. Rosenfeld, if sufficient potassium hydroxide be present to transform the dichromate into monochromate, a precipitate is formed which may be reddish-brown, greenish-yellow, green, or blue according to the proportion of alkali employed—the blue precipitate is copper hydroxide.

M. Rosenfeld supposed that the yellow precipitate just indicated is a basic salt *copper pentoxybischromate*, $7CuO.2CrO_3.5H_2O$; and the green precipitate, which changes to brown on drying, basic *copper hexoxychromate*, $7CuO.CrO_3.5H_2O$—probably both basic salts are mixtures of copper hydroxide and the dioxychromate. The green-coloured substance prepared by C. W. Juch by the action of 2 parts of potassium carbonate and one part of calcium carbonate on a soln. of 48 parts of copper sulphate and 2 parts of potassium dichromate; and that obtained by T. Leykauf by the action of ammonia on a soln. of 2 parts of copper sulphate and one part of potassium dichromate are also mixtures.

According to M. Vuaflart, if copper chromate be treated with aq. ammonia, the dark green soln. does not decolorize on exposure to light, and if evaporated, or cautiously treated with acids, the original chromate is restored. R. Böttger added that if the green soln. be covered with alcohol, it deposits a dark green powder, which, after washing with alcohol, furnishes, according to the analysis of F. J. Malaguti and M. Sarzeau, **copper decamminomonoxybischromate,** $CuO.2CuCrO_4.10NH_3.2H_2O$. The salt was also prepared by A. Kopp. The powder consists of dark green, acicular crystals, which lose ammonia in air; and when heated decompose with a feeble detonation. The salt is decomposed by water. According to P. A. Bolley, F. Dröge, W. Grüne, J. Stinde, and I. C. Zimmermann, the green soln. was formerly used in dyeing.

M. Gröger could not isolate **ammonium copper chromate** of definite composition; the precipitate obtained by treating copper chloride with ammonium chromate, is readily transformed into copper oxychromate. S. H. C. Briggs, and M. Gröger obtained **ammonium copper diamminochromate,** $(NH_4)_2CrO_4.CuCrO_4.2NH_3$, by the action of cupric chloride on a soln. of ammonium chromate containing an excess of ammonia; or of a soln. of copper carbonate in chromic acid on conc. aq. ammonia. The dark green crystals lose water and ammonia at 200°. The salt is hydrolyzed by water. M. Gröger mixed 2 vols. of a soln. of 85·3 grms. of $CuCl_2.2H_2O$ in a litre of water with one vol. of a soln. of 97·2 grms. of potassium chromate in a litre of water. After standing 4 days, at room temp., the precipitate was washed with cold water by suction, and dried at 100°. The brownish-red powder consists of microscopic, four-sided, prismatic crystals of **potassium copper oxyquadrichromate,** $K_2O.4CuO.4CrO_3.3H_2O$, or $K(OH)Cu_2(CrO_4)_2.H_2O$. It is rapidly decomposed by boiling water. A. Knop reported **potassium copper oxytrischromate,** $K_2O.3CuO.3CrO_3.2H_2O$, to be formed by the action of a soln. of potassium dichromate on freshly precipitated copper hydroxide, or by gradually adding a soln. of potassium hydroxide to a mixed soln. of copper sulphate and potassium dichromate. The salt was also prepared by B. Skormin. M. Rosenfeld supposed that this product is impure copper dioxychromate, and M. Gröger, impure potassium copper oxyquadrichromate. C. Gerhardt, and C. Freese supposed the precipitate produced by potassium chromate in a cold soln. of copper sulphate to be potassium copper oxytrischromate. The pale brown powder consists of microscopic, six-sided plates. The salt loses water when heated. Boiling water extracts potassium dichromate. The salt is soluble in a soln. of ammonia and ammonium carbonate. F. Rose, S. Tschelnitz, J. G. Gentele, and G. Zerr and G. Rübencamp mentioned the use of the basic chromate as a reddish-brown pigment under the name *chrome brown.*

According to S. H. C. Briggs, **potassium copper diamminochromate,** $K_2CrO_4.CuCrO_4.2NH_3$, crystallizes out when an ammoniacal soln. of copper chromate to which a large proportion of potassium chromate has been added, is allowed to lose its free ammonia by exposure to air. The crystals were washed by decantation with the mother-liquid, then with dil. ammonia, and finally with alcohol and ether. It is slowly decomposed at 250°, rapidly at 280°; it is decomposed by water; and is soluble in aq. ammonia. M. Prud'homme added a cupric salt to a mixture of sodium hydroxide and chromate, and obtained a yellowish-green soln. of **sodium copper chromate.** A similar soln. is produced by boiling an excess of copper oxide with a soln. of chromic oxide in soda-lye.

According to F. Wöhler and F. Rautenberg,[8] silver chromate can be reduced to *silver subchromate,* possibly Ag_4CrO_4, at ordinary temp. The black powder always contains some metal; the reduction to silver is completed at 50°. The subchromate is coloured red by nitric acid and then dissolved; and with dil. acids a green soln. is formed. W. Muthmann showed that the alleged subchromate is a mixture of ordinary silver chromate and silver.

L. N. Vauquelin [9] obtained **silver chromate,** Ag_2CrO_4, by dropping a dil. soln. of potassium chromate into a conc. soln. of silver nitrate, and washing the dark reddish-brown precipitate—if the silver nitrate soln. be dropped into the chromate soln., the precipitate is orange-red, and is contaminated with the potassium salt, which is very difficult to remove by washing. N. W. Fischer found that silver oxide abstracts chromic acid from a soln. of potassium chromate leaving the liquid alkaline, but a large excess of the oxide does not remove all the chromic acid except when added in the form of its ammoniacal soln. J. Milbauer obtained a 10 per cent. conversion to chromate when a mixture of silver carbonate or oxide and chromic oxide is heated to 480° in oxygen at 12 atm. press. C. Freese obtained silver chromate by boiling silver oxide for some days with a soln. of potassium chromate or dichromate. I. Guareschi obtained silver chromate by the action of a conc. soln. of chromic acid on silver bromide; and M. Gröger, by the action of water on ammonium silver chromate. R. Warington found that when silver dichromate is boiled with water it forms silver chromate; according to E. Jäger and G. Krüss, and B. M. Margosches, the boiling should be continued as long as anything passes into soln. R. Warington also found that when an ammoniacal soln. of silver dichromate is evaporated spontaneously, a greenish crust of the monochromate is formed. F. A. Gooch and R. S. Bosworth showed that silver is precipitated quantitatively as chromate by adding an excess of potassium chromate to a soln. of silver nitrate. The chromate can be purified by dissolving it in aq. ammonia, and reprecipitating it by boiling the soln. G. P. Baxter and co-workers described the preparation of the salt, and added that it can be dried by heating it for 2 hrs. at 225° in a current of dry air. According to A. Lottermoser, by adding $\frac{1}{40}N$-$AgNO_3$

to an excess of $\frac{1}{40}N$-CrO_3, **colloidal silver chromate** is produced; the hydrosol soon becomes turbid. The Chemische Fabrik von Heyden reported that if silver chromate be formed in the presence of proteins as protective colloid, and the soln. dialyzed, or precipitated by the addition of an acid, and afterwards peptized by dil. alkali-lye, the hydrosol is stable. N. R. Dhar and A. C. Chatterji found silver chromate is not peptized by conc. soln. of cane-sugar; and N. R. Dhar and S. Ghosh that it is peptized by ammonium nitrate. N. R. Dhar and A. C. Chatterji studied the adsorption of silver ions by silver chromate. According to F. Köhler, when silver nitrate and ammonium dichromate react as a result of the diffusion which takes place when an aq. soln. of the one salt is placed in contact with a gelatinized soln. of the other, precipitation rings are formed which exhibit rhythmic character. When the ammonium salt is contained in the gelatin layer the ring formation varies with the conc. of the dichromate. At low concentrations, the rings are only partly developed, and at high concentrations they are blurred, but over an intermediate range the ring system is well developed. If the gelatin layer contains the silver salt, similar results are obtained, except that no rings are formed when the conc. is small. The conc. of the gelatin also affects the ring formation in the sense that with increasing conc. the rings become less well defined. It seems probable that rhythmic precipitation phenomena in gelatin-water systems are dependent on the existence of a more or less definite relation between the velocities of diffusion of the reacting substances and the velocity of crystallization of the products of the reaction. In the rhythmical precipitation of silver chromate by means of ammonium dichromate the small crystals of ammonium nitrate which also separate rhythmically are coloured by silver chromate, being yellowish-green to red, according to the conc. Similar coloured crystals are obtained when a soln. of ammonium nitrate containing a little ammonium dichromate is mixed with a drop of silver nitrate and allowed to evaporate on a glass slide. Exactly similar crystals are obtained when potassium dichromate is used. N. R. Dhar and co-workers supposed that the rings are produced by the coagulation of peptized silver chromate. The subject was studied by H. Bechold, H. N. Holmes, E. Hatschek, R. E. Liesegang, N. R. Dhar and A. C. Chatterji, K. C. Sen and N. R. Dhar, A. M. W. Williams and M. R. MacKenzie, T. R. Bolam and M. R. Mackenzie, G. Linck, B. Kisch, M. S. Dunin and F. M. Schemjakin, E. C. H. Davies, A. Janek, A. Steopoe, M. Storz, C. K. Jablcznysky and A. Klein, C. K. Jablczynsky, F. G. Toyhorn and S. C. Blacktin, P. B. Ganguly, R. Fricke, W. Ostwald, F. Köhler, H. McGuigan, E. R. Riegel and M. C. Reinhard, T. R. Bolam and B. N. Desal, S. S. Bhatnagar and J. L. Sehgal, L. N. Mukherjee and A. C. Chatterji, F. M. Shemjakin, H. Westerhoff, F. Pannach, H. W. Morse, W. W. Siebert, D. N. Ghosh, and S. Hedges and R. V. Henley.

Silver chromate varies in colour according to the mode of preparation, and it is described as forming tabular or acicular crystals or a dark green or purple-red crystalline powder. R. Hunt thought that the variations in colour depended on the exposure of the potassium dichromate soln. to light, for he said that the chromate produced by the actinized soln. has a "much more beautiful colour" than when produced by a soln. of dichromate which had not been exposed to light. F. Bush showed that there is no difference in the colour of silver chromate derived from insolated and non-insolated soln. of potassium dichromate, but that the rate of the mixing of the soln. determines the difference in the colour and the physical characteristics of the resulting silver chromate. C. Freese, W. Autenrieth, and B. M. Margosches found that the red variety is produced by precipitation from a silver salt with a chromate or dichromate if the silver is in excess. The result is not affected by temp. On the other hand, when silver dichromate is decomposed by cold or hot water, or when a soln. of silver chromate or dichromate is evaporated, R. Warington, E. Jäger and G. Krüss, W. Autenrieth, and B. M. Margosches observed that green crystals are produced. It has therefore been suggested that silver chromate exists in two forms: (i) red—varying from orange to deep reddish-brown; and (ii) green—varying from dark green to greenish-black, but red in transmitted light, or in the powdered form. It has not been proved whether this is a case of polymorphism, or whether the effect is produced by the varying sizes of the crystalline granules. F. Köhler said that both silver chromate and dichromate can take small quantities of ammonium or potassium nitrate into solid soln. The colour of pure silver chromate is always greenish-black, and the red substance supposed to be a separate modification is really a mixture of silver chromate and a solid soln. of that salt with nitrates. M. Copisarow observed that tree-like, dendritic forms are produced when the precipitate is slowly formed. According to J. W. Retgers, and W. Autenrieth, the red crystals are rhombic with a pleochroism—pale reddish-brown, and brownish-black—they are not isomorphous with silver sulphate but may be so with sodium sulphate.

H. G. F. Schröder gave 5·536 for the sp. gr. of green silver chromate, and 5·523 for that of the red variety; and G. P. Baxter and co-workers gave 5·625 at 25°/4°, for the red crystals; M. L. Dundon, 5·52, and the mol. vol. 60·1 at 26°. M. L. Dundon gave 2 for the hardness, and 575 ergs per sq. cm. for the surface energy at the interface of the solid and water at 26°. According to L. N. Vauquelin, silver chromate melts in the oxidizing flame of the blowpipe; and in the inner flame, it is reduced to silver and chromic oxide. F. Kohlrausch gave for the sp. electrical conductivity of sat. soln. of silver chromate:

	0·26°	14·82°	18°	30·76°	37·30°	75°
Conductivity .	$0{\cdot}0_5667$	$0{\cdot}0_41561$	$0{\cdot}0_4186$	$0{\cdot}0_4350$	$0{\cdot}0_4460$	$(0{\cdot}0_3160)$ mho.

T. R. Bolam and M. R. MacKenzie found the sp. conductivity of soln. of silver chromate and gelatine to be:

Ag_2CrO_4 .	0·00333*N*-	0·00250*N*-	0·00125*N*-	0·00236*N*-	0·00118*N*-	0·00162*N*-
Mho $\times 10^{-3}$.	0·8341	0·6841	0·4636	0·5916	1·3703	0·4207
Gelatine .	3	3	3	1·59	1·59	0·07 per cent.

The conductivities are slightly smaller when the gelatine is set than when it is liquid. The electromotive force of cells with Ag | $0{\cdot}1N$-$AgNO_3$, $10N$-NH_4NO_3, x | Ag, is 0·1483 volt when x is a sat. soln. of Ag_2CrO_4; 0·1469 volt with the same soln. with $0{\cdot}01NaNO_3$; and 0·2247 volt with the salt. soln. of silver chromate plus $0{\cdot}1N$-K_2CrO_4.

For the reducing action of hydrogen, *vide supra.* Silver chromate is very sparingly soluble in ammonia. Expressing the solubilities, S, in milligrams of silver chromate per 100 grms. of water, F. Kohlrausch gave $S=2{\cdot}52$ at 18°, from the electrical conductivity; G. S. Whitby, $S=2{\cdot}56$ at 18°, from colorimetric observations; R. Abegg and A. J. Cox, $S=2{\cdot}0$ at 25°, from potential measurements; R. Abegg and H. Schäfer, $S=2{\cdot}9$ at 25°, from the equilibrium of silver chromate and dichromate; M. S. Sherrill, $S=4{\cdot}1$ at 25°, from the solubility of silver chromate in ammonia; G. S. Whitby, $S=3{\cdot}41$ at 27°, from colorimetric observations; O. Hähnel, $S=5{\cdot}4$ at 35°, from the equilibrium with silver iodate and chromate; G. S. Whitby, $S=5{\cdot}34$ at 50°, from colorimetric observations; and R. F. Carpenter obtained $S=4{\cdot}1$ at 100°. Other observations were made by L. L. de Koninck and E. Nihoul, G. Meinecke, W. G. Young, and R. F. Carpenter. R. Abegg and H. Schäfer obtained for the solubility product $[Ag^{\cdot}]^2[CrO_4']=2{\cdot}64\times10^{-12}$ at 25°, from the equilibrium between silver chromate and dichromate. M. S. Sherrill calculated 9×10^{-12} at 25°, from the solubility of silver chromate in ammonia; and O. Hähnel, $17{\cdot}7\times10^{-12}$ at 35°, from the equilibrium in the reaction $2AgIO_3'+CrO_4'' \rightleftharpoons Ag_2CrO_4+2IO_3'$. B. M. Margosches found that the solubility is diminished by the presence of $Ag^{\cdot}$-ions, or CrO_4''-ions, but in a conc. soln. of potassium chromate the solubility is increased. The solubility in acids is dependent on the grain-size and of the presence of silver chromate. M. L. Dundon observed a 10 per cent. increase in the solubility when the particles are reduced to $0{\cdot}3\mu$ diameter. J. Krutwig found that chlorine liberates oxygen from silver chromate at 200°, forming silver chloride and small red crystals of chromium trioxide. The relatively great solubility of silver chromate with respect to the chloride explains its use as an indicator in the titration of chlorides by a silver salt; so long as an appreciable amount of chloride is present, silver chromate is converted into chloride, but as soon as the chloride is all consumed, the dark red colour of silver chromate appears. According to A. A. Hayes, silver chromate is decomposed by hydrochloric acid and soluble chlorides, and L. L. de Koninck and E. Nihoul said that the decomposition of the chromate by chlorides, bromides, and iodides is quantitative. B. M. Margosches found that the reaction with the alkali halides is fast only with freshly precipitated silver chromate. E. Ramann and H. Sallinger studied the system: $K_2CrO_4 + AgIO_3 \rightleftharpoons KIO_3 + Ag_2CrO_4$. W. R. Hodgkinson and J. Young studied the reduction of the salt by dry sulphur dioxide. A. A. Hayes found that the chromate is decomposed by soln. of sulphates. E. C. Franklin and C. A. Kraus said that silver chromate is insoluble in liquid ammonia. The chromate is slowly dissolved by cold, dil., aq. ammonia, and rapidly by hot, conc., aq. ammonia. The solubility of the chromate in aq. ammonia was measured by M. S. Sherrill, and the results expressed in S mols per litre:

NH_4OH	0·01	0·02	0·04	0·08
S	2·04	4·169	8·595	17·58

The increased solubility with ammonia is attributed to the formation of the soluble complex $Ag(NH_3)_2CrO_4$. E. Mitscherlich, G. Meinecke, and B. M. Margosches obtained from the soln. in conc. aqua ammonia yellow tetragonal crystals of **silver tetramminochromate,** $Ag_2CrO_4.4NH_3$, with the axial ratio $a:c=1:0{\cdot}5478$. H. Topsöe gave 2·717 for the sp. gr. M. S. Sherrill's results are as follows:

HNO_3	0·01	0·02	0·04	0·075
$[Ag^{\cdot}]\times 10^3$	5·808	7·488	10·02	12·41
$[HCrO_4']\times 10^3$	2·245	2·775	3·530	4·220
$[Cr_2O_7']\times 10^3$	0·3775	0·577	0·935	1·333

The tetramminochromate in air loses ammonia more rapidly than the selenate, and potash-lye precipitates fulminating silver from the aq. soln.

B. M. Margosches found that the solubility of silver chromate in nitric acid depends on the age of the salt. L. L. de Koninck and E. Nihoul measured the solubility of the chromate in nitric acid; and R. F. Carpenter, the solubility in soln. of the nitrates. M. S. Sherrill and D. E. Russ said that soln. containing more than 0·075N-HNO_3 form silver dichromate; while F. A. Gooch and R. S. Bosworth said that the chromate is insoluble in dil. nitric acid in the presence of enough potassium chromate to form with the nitric acid, dichromate and nitrate; silver chromate is also said to be insoluble in a soln. of sodium nitrate. F. A. Gooch and L. H. Weed also found the chromate insoluble in a soln. of silver nitrate; aq. soln. containing 3·24 grms. of the salt named per 100 c.c. were found to dissolve at 100° the following amounts:

	Water	$NaNO_3$	KNO_3	NH_4NO_3	$MgNO_3$
Ag_2CrO_4	0·00415	0·00415	0·0124	0·0207	0·0166

B. M. Margosches said that silver chromate is practically insoluble in a soln. of silver nitrate, whilst sodium phosphate soln. form silver phosphate. Silver chromate is practically insoluble in conc. acetic acid, but some is dissolved by dil. acetic acid. A soln. of potassium chromate also dissolves a little silver chromate. A. Jaques studied the reaction with ethyl bromide. B. Guerini found that 11·65 per cent. alcohol dissolves 0·0129 grm. of silver chromate at ordinary temp. According to L. N. Vauquelin, several metals immersed in water and in contact with silver chromate exert a reducing action; and N. W. Fischer said that cadmium separates silver; zinc separates brownish-black, arborescent silver; tin, lead, and iron, a brown spongy mass; arsenic, a brown powder; copper, and mercury have a feeble action; and antimony, none. The precipitates may be contaminated with green chromic oxide; and the liquid may acquire a yellow tinge from the presence of chromic acid. With an ammoniacal soln. of silver chromate, zinc is said to precipitate silver and chromium; cadmium, silver; copper, a grey powder; lead, silver; while tin, iron, and antimony give no precipitation. C. Freese observed that a soln.

of potassium hydroxide extracts all the chromic acid from silver chromate. J. F. G. Hicks and W. A. Craig found that silver chromate undergoes a reaction with an equimolar mixture of fused potassium and sodium nitrates at about 240°, forming basic chromate analogous to a hydrolytic reaction. A state of equilibrium is established; but with fused sodium chloride, at about 870°, the reaction is complete. P. Ray and J. Dasgupta prepared a complex with hexamethylenetetramine. S. J. Thugutt found that aragonite is coloured red whilst calcite is not changed when the minerals are treated with 0·1*N*-$AgNO_3$, and afterwards wetted with a 20 per cent. soln. of potassium dichromate.

M. Gröger obtained a precipitate by the action of an almost sat. soln. of potassium chromate on silver nitrate. The precipitate contained potassium and silver chromates, but he could not decide whether these were mechanically mixed or combined as *potassium silver chromate.* M. Gröger prepared **ammonium silver chromate,** $(NH_4)_2CrO_4.3Ag_2CrO_4$, by dropping a conc. soln. of silver nitrate into a cold, sat. soln. in ammonium chromate, and allowing the mixture to stand for some weeks; he also obtained the same salt by the action of silver nitrate on an ammoniacal soln. of ammonium chromate. The garnet-red powder or hexagonal crystals are decomposed by heat, and by water.

N. A. Orloff [10] prepared an orange-coloured soln. of **gold chromate,** $Au_2(CrO_4)_3$, by adding a soln. of auric chloride to an excess of freshly precipitated silver chromate, and filtering off the silver chloride. If the conc. soln. be evaporated in a desiccator, crystals with the composition $Au_2(CrO_4)_3.CrO_3$ are formed.

In the extraction of chromium by the calcination of a mixture of chromite and limestone, **calcium chromate,** $CaCrO_4$, is formed as an intermediate product—*vide supra.* J. Milbauer observed a 56·9 per cent. conversion to chromate when a mixture of chromic oxide and calcium oxide or carbonate is heated to 480° in oxygen at 12 atm. press. M. R. Nayer [11] and co-workers found that calcium and chromic oxides begin to interact in the presence of air to form calcium chromate at 650°; at 700°, a 95 per cent. yield of chromate is obtained with mixtures containing 2 equivalents of calcium oxide to 1 of chromic oxide and a 60 per cent. yield when the ratio is 1 : 1. In the presence of excess of calcium oxide, equilibrium is attained at about 800°, although pure calcium chromate does not begin to decompose until 1000° is reached. A mixture of calcium oxide, sodium carbonate, and chromium trioxide (1·7 : 0·65 : 1) gave a quantitative yield of chromate in 4 hrs. at 660° and in 5 minutes at 1050°. K. Herrmann and co-workers found that the crystals are rhombic bipyramids and that the crystal unit contains 4 mols, and has a=7·45 A., b=10·3 A., and c=5·85 A. When calcium chromate is decomposed by heat no basic salts are formed. As shown by T. Thomson, and H. Moser, a soln. of calcium chloride slowly forms a precipitate when treated with potassium dichromate; as shown by J. F. Bahr, the precipitate varies in composition, according to the conditions, from $CaCrO_4$ to $5CaCrO_4.K_2CrO_4$. If free acetic acid be present, H. Kämmerer, and F. T. Frerichs observed no precipitation; and F. Kuhlmann found that calcium carbonate is only partially converted into the chromate by a soln. of potassium chromate; lime-water gives no precipitate with a soln. of potassium chromate. F. Mylius and J. von Wrochem obtained the anhydrous chromate by heating the hydrated salt—G. N. Wyrouboff said at 300°—or by warming a supersaturated soln., containing 15 to 20 per cent. $CaCrO_4$, over 36°. The yellow powder consists of fine needles. L. Bourgeois obtained crystals of the anhydrous chromate by melting a mixture of 2 eq. of calcium chloride with an eq. each of potassium and sodium chromates. D. Vorländer and H. Hempel observed no transformation into

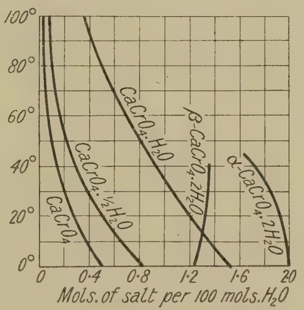

Fig. 48. — The Solubility Curves of Calcium Chromate.

an isotropic form when the alkaline earth chromates are heated. The sat., aq. soln. at 18° has a sp. gr. 1·023 and contains 2·3 per cent. $CaCrO_4$. It is very stable, and is not hydrated by standing for a year in contact with water. Three hydrates have been reported. The percentage solubility, *S*, of stable $CaCrO_4$ is :

	0°	20°	30°	50°	70°	100°
S .	4·31	2·23	1·92	1·11	0·80	0·42

The results are plotted in Fig. 48. By mixing a 15 per cent. soln. of calcium chromate with calcium chloride or glycerol, and rapidly warming to 100°, small, doubly refracting, presumably rhombic crystals of the *hemihydrate*, $CaCrO_4.\frac{1}{2}H_2O$, are formed. They lose water at 400° ; and a soln., sat. at 18°, has 4·4 per cent. $CaCrO_4$, and a sp. gr. of 1·044. The percentage solubility, *S*, of the unstable hemihydrate, Fig. 48, is :

	0°	18°	30°	50°	70°	100°
S .	6·80	4·4	3·66	1·60	1·10	0·80

According to H. von Foullon, the *monohydrate*, $CaCrO_4.H_2O$, is produced when the mother-liquor from the dihydrate is evaporated over 25° ; and F. Mylius and J. von Wrochem obtained it by heating the rhombic β-dihydrate at 12°. The orange-red, rhombic, bipyramidal crystals were found by F. von Foullon to have the axial ratios $a : b : c = 0·6296 : 1 : 0·6404$. G. N. Wyrouboff gave 0·9917 : 1 : 0·7995 and said that the crystals are similar to those of anhydrite. The sp. gr. is 2·793 at 15°, and the mol. vol. 62·4. F. Mylius and J. von Wrochem said that the dark yellow, four-sided, doubly refracting pyramids do not effloresce very much at ordinary temp. The soln. sat. at 18° has a sp. gr. 1·096, and contains 9·6 per cent. of $CaCrO_4$. The percentage solubility, *S*, Fig. 48, of the unstable monohydrate, is

	18°	25°	40°	60°	75°	100°
S .	9·60	9·09	7·83	5·75	4·58	3·10

J. F. Bahr said that when calcium carbonate is treated with a soln. of chromic acid, the dihydrate, $CaCrO_4.2H_2O$, is formed ; and M. Siewert obtained the dihydrate by evaporating in vacuo a soln. of the carbonate in chromic acid. H. von Foullon said that the dihydrate exists in two forms. There is first the labile or *α-dihydrate* obtained by the slow evaporation below 25° of the mother-liquid from the basic salt, or up to 65° in the presence of sulphuric acid. F. Mylius and J. von Wrochem observed that it separates from a supersaturated soln. of calcium chromate at room temp. The sulphur-yellow, monoclinic crystals resemble those of the dihydrated calcium sulphate. There is the stable or β-dihydrate obtained by allowing the α-form to stand in contact with a sat. soln. of calcium chromate ; it also separates when the sat. soln. is allowed to stand for a week. H. von Foullon obtained crystals by evaporating a soln. at 22°. A. Fock also described the preparation of the dihydrate, and according to A. Fock, and H. von Foullon, the pale yellow, rhombic crystals do not resemble those of gypsum. The axial ratios are $a : b : c = 0·6942 : 1 : 0·7388$. The (100)-cleavage is complete. G. N. Wyrouboff could not prepare the dihydrate. M. Siewert said that the dihydrate loses its water when strongly heated, and every time it is heated it becomes cinnabar-red. F. Mylius and J. von Wrochem found that the β-dihydrate at 12° forms the monohydrate. At 18°, the sat. aq. soln. of the α-form contains 14·3 per cent. of $CaCrO_4$ and has a sp. gr. of 1·149 ; while with the β-form there is present 10·3 per cent. of $CaCrO_4$ and the sp. gr. is 1·105. M. Siewert, and H. Schwarz made observations on the solubility. F. Mylius and J. von Wrochem found that the percentage solubilities, *S*, Fig. 48, are :

	0°	20°	45°	0°	20°	40°
S .	14·70	14·20	12·40	9·83	10·20	10·40
	α-dihydrate			β-dihydrate		

The transition temp. for β-dihydrate⇌monohydrate is 10·20° with 14 per cent.

$CaCrO_4$. F. Kohlrausch measured the electrical conductivity of aq. soln. of the salt, while H. H. Hosford and H. C. Jones found for the mol. conductivity, μ mhos, between 0° and 35°, and S. F. Howard and H. C. Jones between 35° and 65°, the following values, when a mol of the salt is dissolved in v litres :

v	. .	8	16	32	128	512	1024	2048	4096
μ	0° .	62	69	77	97	114	119	—	124
	12·5° .	86	96	108	135	160	168	—	173
	25° .	113	126	142	179	212	223	—	230
	35° .	134	147	169	214	255	270	—	279
	65° .	200	229	260	337	412	428	288	—
α	0° .	49·70	85·64	62·19	78·55	91·90	96·12	98·54	100·00
	65° .	65·02	—	77·01	86·41	93·19	96·18	97·60	100·00

The percentage ionization, α, has also been calculated.

H. Caron and D. A. Raquet found dihydrated calcium chromate to be soluble in acids and in dil. alcohol. C. R. Fresenius found that 100 c.c. of 29 per cent. alcohol dissolve 1·216 grms. calcium chromate, and 100 c.c. of 53 per cent. alcohol, 0·88 grm. The anhydrous salt is insoluble in absolute alcohol ; and A. Naumann observed that it is insoluble in acetone. F. Guthrie observed that molten sodium nitrate dissolves 0·547 grm. of the salt. J. F. G. Hicks and W. A. Craig found that equimolar mixture of fused sodium and potassium nitrates, at about 870°, reacts with calcium chromate forming basic salts and entering into a state of equilibrium analogous to a hydrolytic reaction. L. Kahlenberg and W. J. Trautmann found that when calcium chromate is mixed with silicon and heated in the electric arc furnace there is a strong reaction, but in the bunsen burner there is a slight reaction. J. B. Hannay obtained *potassium calcium sulphatochromates*, $K_2CrO_4.CaSO_4,H_2O$; $2K_2CrO_4.CaSO_4$; and $K_2CrO_4.CaSO_4.Na_2SO_4.H_2O$. H. von Foullon obtained the basic salt, **calcium oxychromate,** $CaO.CaCrO_4.3H_2O$, by warming to 50°–60°, a soln. of calcium carbonate in a dil. aq. soln. of chromic acid ; or, according to F. Mylius and J. von Wrochem, from a soln. of chromic acid supersaturated with calcium hydroxide. The lemon-yellow, monoclinic prisms have the axial ratios $a:b:c=1·0311:1:0·6500$, and $\beta=98°\ 13'$. 100 parts of water dissolve 0·435 part of the salt.

K. S. Nargund and H. E. Watson found that when calcium chromate is heated to 1030° at less than 20 mm. press., **calcium dichromitochromate,** $3CaO.Cr_2O_3.CrO_3$, is formed ; if the press. be 2 mm., **calcium hexachromito*bis*chromate,** $8CaO.3Cr_2O_3.2CrO_3$, is produced ; and at lower press., **calcium tetrachromitochromate,** $5CaO.2Cr_2O_3.CrO_3$, results, and it has no measurable dissociation press. at 1030°. If calcium chromate mixed with lime is heated, **calcium oxy*bis*chromate,** $CaO.2CaCrO_4$, is formed, and it readily decomposes, forming **calcium dichromito*sexies*chromate,** $12CaO.Cr_2O_3.6CrO_3$, with a dissociation press. of 270 mm. at 910° ; and it decomposes, forming **calcium dichromito*quater*chromate,** $9CaO.Cr_2O_3.4CrO_3$, with a dissociation press. of 22 mm. at 920°. This product is also formed when a mixture of calcium oxide and chromate is heated in air ; the black compound is soluble in dil. acids, and when heated to 1030° furnishes **calcium dichromito*tris*chromate,** $6CaO.Cr_2O_3.3CrO_3$. A mixture of calcium chromate and chromic oxide yields **calcium dichromito*bis*chromate,** $2CaO.Cr_2O_3.2CrO_3$, with a dissociation press. of 150 mm. at 1030°, and finally a chromite.

A. Duncan found that a soln. of freshly burnt lime in an aq. soln. of potassium dichromate, when evaporated, gives orange-yellow crystals of **potassium calcium chromate,** $K_2CrO_4.CaCrO_4$, which are the *monohydrate* if the crystallizing soln. is boiling, and the *dihydrate*, if the soln. is at 80°. E. Schweizer obtained the dihydrate by saturating a not too conc. soln. of potassium dichromate with calcium hydroxide, passing a current of carbon dioxide through the clear liquid, and evaporating the soln. at 30°–40°. The crystals of the dihydrate are lemon-yellow. There is formed at the same time a brown crystalline crust of $K_2CrO_4.4CaCrO_4.2H_2O$, which is easily separated from the lemon-yellow crystals of the dihydrate. M. Gröger obtained it by evaporating on a water-bath an almost sat. soln. of potassium chromate containing 4 eq. of N-$CaCl_2$. M. Barre found that by the direct action of calcium chromate on soln. of potassium chromate at temp. below 45°, large rhombic prisms of the salt $K_2CrO_4.CaCrO_4.2H_2O$ are obtained. These, in contact with a soln. of potassium chromate at 60°, slowly disappear, and small, hexagonal prisms of the anhydrous salt, $K_2CrO_4.CaCrO_4$, are formed. Both these salts are decomposed by water. F. Stolba, and F. Mohr made some observations on this salt. G. N. Wyrouboff said that the crystals are dimorphous since there is an α-form occurring in yellow triclinic pinacoids $a:b:c=0\cdot6591:1:0\cdot4383$, and $\alpha=78°\ 16'$, $\beta=101°\ 3'$, and $\gamma=83°\ 8'$. The (101)-cleavage is complete, and the $(10\bar{1})$-cleavage is distinct. The sp. gr. is 2·411 at 15°, and the mol. vol. 160·5. The brown β-form also occurs in triclinic pinacoids with the axial ratios $a:b:c=0\cdot7516:1:0\cdot8807$, and $\alpha=86°\ 0'$, $\beta=94°\ 41'$, and $\gamma=81°\ 37'$. The (010)-cleavage is nearly complete. The sp. gr. is 2·596 at 15°, and the mol. vol. 149·3. The α-form is produced before the β-form. A. Rakowsky said that the α-form is not stable above 20°, and G. N. Wyrouboff added that it begins to give off water at 100°, and is completely dehydrated at 120°. A. Rakowsky found that the α-variety is less soluble than the β-form. Water at 0° and 15° dissolves respectively 23·06 and 25·06 parts of the α-form, and respectively 23·01 and 24·45 parts of the β-form. The heats of soln. of the α- and β-forms are, respectively, —6·99 Cals. and —5·45 Cals. H. G. F. Schröder gave 2·502 for the sp. gr. of the salt. E. Schweizer said that the salt loses water when heated, and becomes reddish-yellow while hot. It melts at a dull red-heat and forms, when cold, a crystalline cake. A. Duncan said that the salt which has been fused dissolves readily in water, but not in alcohol; and M. Gröger added that the salt is soluble in cold water without decomposition. E. Schweizer found that the aq. soln. decomposes on evaporation forming $K_2CrO_4.4CaCrO_4.2H_2O$. According to E. Schweizer, **potassium calcium quinquemonochromate,** $K_2CrO_4.4CaCrO_4.2H_2O$, is obtained, as indicated above. H. G. F. Schröder gave 2·787 for the sp. gr. In addition to the *dihydrate*, G. N. Wyrouboff obtained yellow *hemiheptahydrate*, $K_2CrO_4.4CaCrO_4.3\frac{1}{2}H_2O$, by saturating a cold, conc. soln. of potassium dichromate with calcium oxide, and allowing the filtered soln. to stand over sulphuric acid in a warm place. J. F. Bahr found that **potassium calcium seximonochromate,** $K_2CrO_4.5CaCrO_4$, separated during the evaporation of a soln. of calcium chloride and potassium chromate. The yellow, granular salt decrepitates when heated, and dissolves in water. M. Gröger could not prepare **ammonium calcium chromate.**

A. Osann found in the caliche deposits of Atacama, Chili, a salt which had a composition corresponding with **calcium iodatochromate,** $7Ca(IO_3)_2.8CaCrO_4$, and the mineral was called **dietzeite**—after A. Dietze, who had previously observed the complex salt in the same deposit. B. Gossner and F. Mussgnug's examination showed that the composition approximates $Ca(IO_3)_2.CaCrO_4$, and B. Gossner considered that the iodate and chromate furnish isomorphous mixtures. According to A. Osann, the colour of dietzeite is golden-yellow. The crystals are prismatic and tabular; but the mineral is commonly fibrous to columnar. The axial ratios of the monoclinic crystals are $a:b:c=1\cdot3826:1:0\cdot9515$, and $\beta=73°\ 28'$. B. Gossner and F. Mussgnug found that the X-radiograms correspond with $a=10\cdot6$ A., $b=7\cdot30$ A., $c=14\cdot03$ A., and $\beta=106°\ 32'$. This gives the axial ratios $a:b:c=1\cdot392:1:1\cdot922$; the elementary cell has the volume 997×10^{-24} c.c. According to A. Osann, the (100)-cleavage is imperfect; the lustre is vitreous; and the fracture, conchoidal. The optical character is positive and the optical axial angle $2G=87°$ to 88°. The hardness is 3 to 4; and the sp. gr. 3·698. B. Gossner and F. Mussgnug calculated 3·617 for the sp. gr. The salt is soluble in hot water, and the soln., on cooling, deposits crystals of $Ca(IO_3)_2.6H_2O$.

When a soln. of strontium chloride is treated with potassium chromate, **strontium chromate,** $SrCrO_4$, is precipitated. J. D. Smith observed that no precipitation occurs with dil. soln.; J. W. Döbereiner, that aq. soln. of strontium hydroxide gave no precipitate; and H. Kämmerer, and F. T. Frerichs, that no precipitation occurs if the soln. be acidified with acetic acid, but H. Caron and D. A. Raquet found that if the soln. be neutralized with ammonia, and treated with alcohol, strontium chromate is precipitated. A. de Schulten obtained the crystalline salt by dissolving 25 grms. of $Sr(HO)_2.4H_2O$ and 30 grms. of potassium dichromate in 100 c.c. of water heated on a water-bath, and adding drop by drop 0·3 per cent. ammonia. L. Bourgeois obtained the crystalline salt by melting a mixture of strontium chloride and sodium and potassium chromates as in the case of the calcium salt. The pale yellow powder consists of monoclinic prisms or plates which, according to A. de Schulten, have the axial ratios $a:b:c=0·9666:1:0·9173$, and $\beta=102° 43'$. E. Herlinger studied the structure of the crystals; and L. Bourgeois said that they are isomorphous with those of barium and calcium chromates, and with the sulphate. W. Autenrieth observed that strontium chromate furnishes bundles of long, slender, highly refracting needles, or, when separating from very dil. soln., it furnishes thick prisms of hexagonal habit. The latter appears to be a labile form which is slowly converted into the former. H. G. F. Schröder gave 3·353 for the sp. gr., and A. de Schulten, 3·895 at 15°. According to C. R. Fresenius, 100 parts of water at 15° dissolve 0·12 part of strontium chromate; and I. Meschtschersky, 0·119 part at 16°. F. Kohlrausch found that 100 c.c. of a soln. at 18° contain 0·12 grm. $SrCrO_4$; and C. Reichard, that water at 10° dissolves 0·465 per cent.; at 20°, 1·000 per cent.; at 50°, 2·417 per cent.; and at 100°, 3·000 per cent. F. Ransom made some observations on this subject. H. Caron and D. A. Raquet said that the solubility in water is lowered by the addition of alcohol. C. Reichard found that the chromate is freely soluble in hydrochloric, nitric, or aq. chromic acids; W. Autenrieth, and H. Caron and D. A. Raquet, that it is freely soluble in acetic acid—I. Meschtschersky said sparingly soluble. C. R. Fresenius observed that 100 c.c. of 29 per cent. alcohol dissolve 0·0132 grm. of strontium chromate; and 100 c.c. of 53 per cent. alcohol, 0·002 grm. E. Dumesnil said that it is readily soluble in a soln. of ammonium chloride, so that 100 c.c. of a sat. soln. of ammonium chloride, on boiling, easily dissolve a gram of the chromate. C. R. Fresenius observed that 100 parts of a 0·5 per cent. soln. of ammonium chloride at 15° dissolve 0·195 part of strontium chromate; 100 parts of 1 per cent. acetic acid, 1·57 part; and 100 c.c. of 0·75 per cent. acetic acid mixed with a little ammonium chromate, dissolve 0·287 part. F. Guthrie added that molten sodium nitrate dissolves 2·133 per cent. of strontium chromate. Strontium chromate has been used as a pigment—*lemon-yellow, strontian yellow, jaune de strontiane, giallo di stronziana,* and *amarillo di estronciana.*

M. Gröger prepared **potassium strontium chromate,** $K_2CrO_4.SrCrO_4$, by the action of an almost sat. soln. of potassium chromate containing 4 eq. of N-$SrCl_2$. M. Barre also prepared this salt. The yellow crystals are decomposed by water into the constituent salts. M. Barre found that the complex salt is stable at 11·5° in contact with a soln. containing 2·914 parts of potassium chromate per 100 parts of water; at 27·5°, 4·123 parts; at 50°, 5·942 parts; at 76°, 7·920 parts; and at 100°, 9·784 parts. He also obtained **ammonium strontium chromate,** $(NH_4)_2CrO_4.SrCrO_4$, by the action of a soln. of strontium chloride on one of ammonium chloride. The pale yellow crystals are decomposed by water.

When an aq. soln. of a barium salt, or baryta-water is treated with alkali mono- or di-chromate, a pale yellow precipitate of **barium chromate,** $BaCrO_4$, is deposited. J. D. Smith said that the precipitation with a barium salt is as delicate a test for chromate as it is for sulphates. F. T. Frerichs, and H. Kämmerer obtained a complete precipitation in the presence of acetic acid or sodium acetate. P. D. Chrustschuff and A. Martinoff observed that 12 per cent. of barium sulphate is converted into barium chromate by contact for 47 min. with a soln. containing potassium sulphate and potassium chromate in eq. proportions, whilst 1·5 per cent. of barium chromate is converted into barium sulphate in the same time in contact with a similar soln. The limits of the reaction do not attain more than 22 per cent. and 17 per cent. respectively, even after 40 to 45 hrs. M. Scholtz and R. Abegg found that at 100°, equilibrium between barium sulphate and potassium chromate in aq. soln. is established very slowly; it is reached more rapidly when a soln. of potassium sulphate acts on barium chromate. The ratio between the quantities of potassium chromate and sulphate in soln. when equilibrium is reached depends on the relative quantities of the solid barium salts, from which it appears that the precipitate consists of a solid soln. The relation $[K_2CrO_4][K_2SO_4] = 1{\cdot}3[BaCrO_4][BaSO_4]$ appears to hold. H. Rose found that an excess of alkali chromate will completely transform barium carbonate into the chromate; and F. J. Malaguti made observations on this subject, and J. Morris studied the precipitation of barium from a soln. of its chloride by the addition of a mixture of potassium carbonate and chromate. M. Scholtz and R. Abegg showed that in the equilibrium between potassium chromate and barium carbonate, the ratio of the conc. of potassium carbonate and chromate also varies in the same way as the ratio between the numbers of mols. of barium carbonate and chromate in the precipitate, but the two ratios are not proportional. There is, however, always relatively less chromate in the soln. than in the precipitate. Barium chromate and sulphate are about equally soluble, and both are much less soluble than the carbonate. A. Pool also studied this system. J. F. Bahr obtained crystalline barium chromate by decomposing barium dichromate with water; A. de Schulten, by heating on a water-bath a soln. of 20 grms. of barium nitrate in a litre of water mixed with 10 c.c. of nitric acid of sp. gr. 1·2, and adding 2 litres of a soln. of 10 grms. of potassium dichromate; and L. Bourgeois by melting 2 eq. of barium chloride with one eq. each of sodium, and potassium chromates. J. Milbauer found that when a mixture of barium oxide or carbonate and chromic oxide is heated to 480° in oxygen at 12 atm. press. there is a 52·8 per cent. conversion to chromate. J. A. Atanasiu found that in the electrometric titration of soln. of barium chloride soln. and potassium chromate there is a break corresponding with normal barium chromate. O. Ruff and E. Ascher studied the joint precipitation of lead and barium chromates; barium and strontium chromates; and barium sulphate and chromate; and O. Ruff, the X-radiograms.

The pale lemon-yellow barium chromate was found by H. Moser to become dark yellow when heated. L. Bourgeois said that the rhombic prisms are isomorphous with barium sulphate; and A. de Schulten gave for the axial ratios of the rhombic plates $a:b:c = 0{\cdot}8038:1:1{\cdot}2149$. F. Rinne studied the crystals of barium chromate; and M. Copisarow observed tree-like, dendritic forms are produced when the precipitate is slowly formed. The sp. gr. observed by H. G. F. Schröder is 4·296–4·304; C. H. D. Bödecker, 3·90 at 11°; E. Schweizer, 4·5044; A. Schafarik, 4·49 at 23°; L. Bourgeois, 4·60; and A. de Schulten, 4·498 at 15°. P. Bary, and J. Precht found that the salt is not fluorescent when exposed to X-rays. F. Kohlrausch gave for the sp. conductivity of sat. soln. $0{\cdot}0_5114$ mho at $-0{\cdot}88°$; $0{\cdot}0_5297$ mho at 16·07°, $0{\cdot}0_5317$ mho at 17·42°; and $0{\cdot}0_5499$ mho at 28·08°. The solubility of the salt in water is very small; F. Kohlrausch and co-workers calculated from observations on the electrical conductivity, the following solubilities, S grms. per litre:

	−0·88	16·07°	17·42°	18°	28·08°
S . .	2·04	3·37	3·48	3·53	4·36

For the equilibrium between barium chromate and dichromate, *vide supra*, chromic acid. I. Meschtschersky found that a litre of water dissolved 4·3 mgrms. at 100°. C. R. Fresenius said that at 0°, a litre of water dissolves 1·19 mgrms. The salt is less soluble after it has been ignited. E. Schweizer said that in that state a litre of water dissolves 0·62 mgrm. L. M. Henderson and F. C. Kracek pointed out that the solubilities of the alkaline earth chromates decrease as the at. wt. of the alkaline earth metal. Thus, at 15°, the solubilities of the anhydrous calcium, strontium and barium chromates are of the order 25, 1·2, and 0·0033 grms. per litre respectively. The solubility of **radium chromate** seems to follow the rule, and a separation of radium and barium can be effected by fractional precipitation as chromates. The partition factor for acidic soln. is about 15·5.

The soln. of barium chromate in hydrochloric, or nitric acid or in an excess of chromic acid, was found by J. F. Bahr, H. Caron and D. A. Raquet, and K. Preis and B. Rayman to become orange-red owing to the formation of dichromate, but the monochromate is reprecipitated from this soln. by ammonia. The statement with reference to the solubility in soln. of chromic acid was disputed by L. Schulerud, and W. Autenrieth. E. Schweizer said that the salt is insoluble in a soln. of potassium dichromate, and 100 parts of a 10 per cent. soln. of chromic acid dissolve 0·055 part of chromate. When sulphur dioxide is passed over heated barium chromate W. R. Hodgkinson and J. Young found that chromium sulphate is formed as the chromate is decomposed. N. W. Fischer observed that barium chromate is not decomposed by cold sulphuric acid, but is decomposed with difficulty by the hot acid; he also stated that aq. soln. of sulphates do not affect the chromate, and the action is only slight with hot soln. H. Schwarz found that about a quarter mol is decomposed by a mol of conc. sulphuric acid to form, according to L. Bourgeois, barium sulphate and chromium trioxide. Observations by P. D. Chrustschoff and A. Martinoff, M. Scholtz and R. Abegg are indicated above. The transformation of the chromate into carbonate by the fusion with sodium carbonate, or by digestion with a soln. of the carbonate, was discussed by H. Rose, F. J. Malaguti, M. Scholtz and R. Abegg—*vide supra*. K. W. Flöroff gave $1{\cdot}6\times10^{-11}$ for the solubility product at 18°. According to H. Golblum, the equilibrium constant $K=[K_2CO_3]/[K_2CrO_4]$ in the reaction: $K_2CO_3+BaCrO_4\rightleftharpoons BaCO_3+K_2CrO_4$, is not constant but decreases to a minimum value. The deviation from the simple mass law is ascribed to the ionization of the salts. The heat of the reaction, calculated from the equilibrium constants at 25° and 40°, is 5997 cals. E. Carrière and P. Castel found that the equilibrium constant $K=[CrO_4]^2[H]^2/[Cr_2O_7]$ with barium chromate in acid soln. is 3×10^{-15}.

B. Guerini observed that $0{\cdot}22\times10^{-4}$ gram-equivalent of barium chromate are dissolved by a litre of 45 per cent. alcohol, and A. Naumann observed that it is insoluble in acetone, and in methyl acetate. I. Meschtschersky, and H. Baubigny said that the chromate is soluble in acetic acid; while H. Caron and D. A. Raquet said that barium chromate is insoluble in acetic acid and soln. of alkali chromate, but partially soluble in a mixture of dichromate and acetic acid. According to C. R. Fresenius, the presence of acetic acid increases the solubility of barium chromate, for 100 parts of water containing one part of acetic acid dissolve 0·0027 part of chromate. E. Schweizer said that 100 parts of 5 per cent. acetic acid dissolve 0·02725 part of chromate, and with 10 per cent. acetic acid, 0·0503 part. C. R. Fresenius said that ammonium salts also make the chromate more soluble, thus 100 parts of water containing 0·5 per cent. of ammonium chloride dissolve 0·00435 part of the chromate; water with 0·5 per cent. of ammonium nitrate dissolves 0·00222 part of chromate; water with 0·75 per cent. of ammonium acetate dissolves 0·002 part of chromate; and water with 1·5 per cent. of ammonium acetate dissolves 0·00417 part of chromate. E. Fleischer found that barium chromate is readily soluble in soln. of alkali tartarate or citrate; L. Bourgeois that it is decomposed with difficulty by alkali hydroxides; and F. Guthrie that molten sodium nitrate dissolves 0·205 per cent. $BaCrO_4$. K. W. Flöroff studied the adsorption of potassium chromate by barium sulphate, and showed that the reaction, particularly for conc. soln., is complex—probably $2BaSO_4+K_2CrO_4=BaSO_4.BaCrO_4+K_2SO_4$. L. Kahlenberg and W. J. Trautmann observed that when mixed with silicon, there is a strong reaction at a cherry-red-heat, and in the electric arc. C. Zerr and G. Rübencamp mentioned the use of barium chromate as a pigment—*ultramarine yellow, lemon yellow, permanent yellow, jaune de baryte, giallo di barite, amarillo di barita, oltremare giallo, outremer jaune, amarillo ultrames, Citrongelb.* M. A. Iljinsky and co-workers studied the adsorption of barium chromate by silk, wool, and cotton fibres.

M. Gröger prepared **potassium barium chromate,** $K_2CrO_4.BaCrO_4$, by shaking an almost sat. soln. of potassium chromate with a cold, sat. soln. of barium chloride. The pale yellow granules are decomposed by water. M. Barre also prepared this salt. M. Gröger also made **ammonium barium chromate** by precipitation with soln. of ammonium chromate and barium chloride. The precipitate is at first amorphous, but soon forms six-sided plates. The salt is decomposed by water. L. Bourgeois reported **barium strontium chromate,** $BaSr(CrO_4)_2$, to be formed in prismatic crystals by the process used for strontium calcium chromate—*vide supra ;* similarly also with **barium calcium chromate,** $BaCa(CrO_4)_2$. L. H. Duschak found that a crystalline precipitate of barium and strontium chromates of definite composition is formed in a sat. soln. of barium chromate containing given conc. of strontium chromate and acetic acid. Diffusion takes place within this substance, and that, therefore, it must either be regarded as a solid soln., or else diffusion must be recognized as a possible property of isomorphous mixtures. L. M. Henderson and F. C. Kracek [12] discussed the separation of radium and barium by the fractional precipitation of barium chromate and **radium chromate.**

A. Atterberg [13] found that beryllium hydroxide dissolved in an aq. soln. of chromic acid to form a deep red liquid from which no crystals can be obtained ; and that when a soln. of beryllium sulphate is treated with potassium chromate, the precipitate first formed dissolves with stirring, and finally there is deposited a yellow basic salt. J. C. G. de Marignac treated soln. of potassium dichromate with beryllium sulphate and obtained a precipitate of variable composition. A. Atterberg found that beryllium carbonate is decomposed by a soln. of potassium dichromate, carbon dioxide is evolved, and a basic chromate is formed. This when washed and dried gives a pale yellow powder approximating $14BeO.CrO_3.23H_2O$. It loses 5 mols. of water at 100° ; 16 mols. at 300° ; and all is lost at dull redness. At a higher temp. oxygen is given off. B. Glassmann obtained **beryllium dodecahydroxychromate,** $6Be(OH)_2.BeCrO_4$, as a yellow powder by heating the normal chromate with water, or by treating a soln. of beryllium sulphate with ammonium chromate. It is insoluble in water, but soluble in chromic acid soln. Normal **beryllium chromate,** $BeCrO_4.H_2O$, was obtained by neutralizing a conc. soln. of chromic acid with beryllium carbonate, and evaporating the liquid. The reddish-yellow, monoclinic plates are hydrolyzed by water. B. Bleyer and A. Moormann could not obtain either of the two salts described by B. Glassmann. The precipitation of beryllium sulphate by potassium chromate yields impure, amorphous products of varying composition, whilst the precipitate from the chloride has the composition $15BeO.CrO_3.12H_2O$, independently of the proportions of the reacting substances. Beryllium hydroxide and chromic acid yield only resinous masses, but the clear soln. contains beryllium and chromium in the ratio 1 : 1. N. A. Orloff obtained $9BeO.BeCrO_4.16H_2O$ and $20H_2O$, and $14BeO.BeCrO_4.31H_2O$, from a soln. of beryllium sulphate and potassium chromate ; $12BeO.BeCrO_4.16H_2O$ from a soln. of beryllium hydroxide in chromic acid and potassium chromate ; and $5BeO.BeCrO_4.14H_2O$, as a precipitate by adding alcohol to a soln. of beryllium hydroxide in chromic acid. Hence, beryllium chromate is gradually hydrolyzed by water without forming any definite basic salt. H. C. Creuzberg prepared beryllium tridecoxychromate, $BeCrO_4.13BeO.23H_2O$, by precipitation.

L. N. Vauquelin [14] prepared **magnesium chromate,** $MgCrO_4$, by crystallization from a soln. of magnesia in chromic acid. J. Milbauer observed an 82·7 per cent. conversion to chromate when chromic oxide mixed with magnesium oxide or carbonate is heated to 480° in oxygen at 12 atm. press. The orange-yellow, six-sided prisms of the chromate crystallized in aq. soln. were said by H. Kopp to be isomorphous with magnesium sulphate, and his analysis corresponded with *heptahydrate*, $MgCrO_4.7H_2O$. A. Murmann gave for the axial ratios of the rhombic, bisphenoidal crystals $a : b : c = 0·9901 : 1 : 0·5735$. The (010)-cleavage is perfect. W. J. Grailich gave for the optic axial angle $2V = 75° 28'$. The optical character is negative. E. Dittler obtained overgrowths with magnesium sulphate. H. G. K. Westenbrink found that the rhombic bisphenoidal crystals have four mols. in unit cell, and that the dimensions are $a = 11·89$ A., $b = 12·01$ A., and $c = 6·89$ A. Observations on the crystals were made by H. Dufet, and L. Longchambon ;

C. Gaudefroy studied the corrosion figures; and A. Fock, the solid soln. of the heptahydrates of magnesium chromate and sulphate. H. Kopp gave 1·66 for the sp. gr. at 15°; C. H. D. Bödeker, 1·75; and F. W. Clarke, 1·761 at 16°. F. Mylius and R. Funk observed that a sat. soln. containing 4·2 per cent. $MgCrO_4$ had a sp. gr. 1·422; A. Heydweiller found the sp. gr. at 18°/18° of soln.:

$MgCrO_4$.	0·1234*N*-	0·247*N*-	0·617*N*-	1·1234*N*-	2·468*N*-	4·936*N*-
Sp. gr. .	1·00857	1·01710	1·04178	1·0818	1·1596	1·3052

K. F. Slotte found the sp. gr. of soln. of magnesium chromate with 12·31, 21·86, and 27·71 per cent. of chromate to be respectively 1·0886 at 13·6; 1·1641 at 14·5°; and 1·217 at 13·6°; and the viscosities (water 100) to be respectively 151·8, 227·8, and 317·7 at 10°; 115·4, 170·9, and 235·6 at 20°; 92, 134·7, and 182·8 at 30°; and 75, 108·6, and 145·5 at 40°. W. Kohlrausch said that 100 c.c. of a sat. soln. at 18° contain 60 grms. $MgCrO_4$; and G. N. Wyrouboff found that the heptahydrate lost 2 mols. of water in air, 3 mols. at 120°; but expulsion of the last mol. of water is attended by the decomposition of the salt. M. R. Nayar and co-workers observed that very little chromate is formed when a mixture of magnesia and chromic oxide is heated below 600°; at 650°, magnesium chromate decomposes into basic chromites (*q.v.*). H. Topsöe and C. Christiansen found the indices of refraction for the *D*-line to be $\alpha=1·5211$, $\beta=1·5500$, and $\gamma=1·5680$; while for the *C*-line, $\alpha=1·5131$, $\beta=1·4315$, and $\gamma=1·5633$. A. Fock gave for the refractive indices, μ, and the optic axial angle, $2V$, of mixtures of magnesium sulphate and chromate containing the eq. per cent. of $MgCrO_4.7H_2O$,

	$MgCrO_4 . 7H_2O$	0	52	15·8	18·5	31·6	35·9	43·7	100 per cent.
μ	α . .	0·4319	1·4353	1·4388	1·4408	1·4457	1·4543	1·6432	1·5221
	β . .	1·4519	1·4579	1·4618	1·4632	1·4727	1·4778	1·4934	—
	γ . .	1·4602	1·4635	1·4666	1·4697	1·4844	1·4881	—	1·5680
$2V$	. .	51° 28′	53° 32′	53° 58′	55° 40′	57° 16′	60° 14′	69° 52′	75° 28′

P. Walden gave for the eq. conductivity, λ mho, at 25° with a mol of the salt in v litres:

v . . .	32	64	128	256	512	1024
λ . . .	80·6	90·6	98·9	107·2	114·3	119·9

while H. Clausen, and A. Heydweiller obtained for conc. soln., at 18°:

v . . .	0·203	0·405	0·81	1·62	4·05	8·1
λ . . .	12·23	24·85	34·17	41·07	48·09	54·86

W. J. Grailich and V. von Lang found the diamagnetism to be strongest in the direction of the (010)-axis. M. Wein studied the electrical conductivity. A. Naumann said that the salt is soluble in acetone. G. N. Wyrouboff prepared the *pentahydrate*, $MgCrO_4.5H_2O$, from the heptahydrate as indicated above; or by crystallizing an aq. soln. above 30°. The yellow crystals are stable, and do not effloresce in air. They are triclinic pinacoids with the axial ratios $a:b:c=0·5883:1:0·5348$, and $\alpha=82°\ 43'$, $\beta=108°\ 14'$, and $\gamma=103°\ 51'$. They are isomorphous with pentahydrated cupric sulphate. No cleavage was observed. The sp. gr. is 1·954. For the action of heat, *vide supra.*

M. Gröger prepared **ammonium magnesium chromate,** $(NH_4)_2Mg(CrO_4)_2.6H_2O$, from soln. of ammonium chromate and magnesium chloride; and F. J. Malaguti and M. Sarzeau, by adding ammonia to a soln. of magnesium chromate in aq. chromic acid until the hydroxide begins to separate, and then evaporating. The pale yellow crystals were found by A. Murmann to be monoclinic prisms with the axial ratios $a:b:c=0·7511:1:0·4931$, and $\beta=106°\ 31'$; and M. W. Porter, $0·7517:1:0·4935$ and $\beta=106°\ 07'$. A. E. H. Tutton and M. W. Porter found the topic axial ratios $\chi:\psi:\omega=6·3751:8·4811:4·1761$. The optic axial angles:

	red-light	Li-	*C*-	Na-	Tl-	Cd-lines
$2E$ . . .	16° 29′	9° 50′	14° 29′	45° 8′	66° 1′	77° 43′
$2V$ . . .	10° 47′	6° 15′	8° 54′	26° 53′	38° 57′	44° 37′

They also investigated the effect of temp. on these angles. M. W. Porter found with 0, 43·85, 72·52, and 100 per cent. $(NH_4)_2Mg(CrO_4)_2.6H_2O$, the axial ratios 0·7499 : 1 : 0·4935, and β=106° 15′; 0·7476 : 1 : 0·4928, and β=106° 32′; 0·7451 : 1 : 0·4930, and β=106° 55′; and 0·7409 : 1 : 0·4924, and β=107° 6′ respectively; and the respective refractive indices α=1·6363, β=1·6371, γ=1·6531; α=1·554, β=1·557, γ=1·560; α=1·491, β=1·493, γ=1·495; and α=1·4716, β=1·4730, γ=1·4786. S. Rosch and M. Stürenburg studied the optic axial angles. F. W. Clarke gave 1·84 for the sp. gr. at 16°; and M. W. Porter, 1·835 at about 16°. The mol. vol. is 215·92. C. Schaefer and M. Schubert observed in the ultra-red reflection spectrum a complex maximum at 11·3μ to 11·42μ; and in polarized light the maximum falls into three groups—11·46μ parallel to the a-axis, 11·28μ parallel to the b-axis, and 10·36μ parallel to the c-axis. A. E. H. Tutton and M. W. Porter found for the indices of refraction:

	Li-	C-	Na-	Tl-	Cd-light
α . . .	1·6248	1·6265	1·6363	1·6489	1·6571
β . . .	1·6250	1·6267	1·6371	1·6509	1·6602
γ . . .	1·6390	1·6411	1·6531	1·6687	1·6799

The refractive indices at 80° were about 0·0023 lower than for ordinary temp. The optical properties of isomorphous mixtures of ammonium magnesium sulphate and chromate were examined. F. Rüdorff's diffusion experiments showed that the salt is more or less dissociated in aq. soln. G. Canneri prepared **guanidine magnesium chromate,** $(CH_5N_3)_2.H_2CrO_4.MgCrO_4.6H_2O$, isomorphous with the sulphate. A. Stanley evaporated a soln. obtained by treating a soln. of sodium dichromate with a magnesium salt, and obtained yellow, four-sided prisms and plates of **sodium magnesium chromate,** $Na_2CrO_4.MgCrO_4.3H_2O$. The salt gives off all its water below 200° leaving the reddish-brown, pulverulent anhydride. The *trihydrate* is freely soluble in water and alcohol, but insoluble in ether.

T. Thomson, and E. F. Anthon prepared **potassium magnesium chromate,** $K_2CrO_4.MgCrO_4.2H_2O$, by evaporating a soln. of potassium dichromate mixed with magnesia; M. Gröger, by treating an almost sat. soln. of potassium chromate with a soln. of magnesium chloride. G. N. Wyrouboff said that the *dihydrate* is obtained if the soln. be evaporated over 18°. The triclinic, pinacoidal crystals were found by G. N. Wyrouboff to have the axial ratios $a:b:c$=0·6551 : 1 : 0·4326, and α=84° 35′, β=102° 44′, and γ=86° 38′. Twinning occurs about the (101)-, $(10\bar{1})$-, and (100)-planes; and the (101)- and $(10\bar{1})$-cleavages are distinct. The optical character is negative. H. G. F. Schröder gave 2·600 for the sp. gr.; E. F. Anthon, 2·59 at 19°; and G. N. Wyrouboff, 2·602 at 16°, and for the mol. vol. 142·5. E. F. Anthon observed that when the salt is heated, it becomes orange-yellow, and melts at dull redness forming a dark red liquid; and E. Schweizer represented the decomposition at a red-heat by $2K_2Mg(CrO_4)_2=2K_2CrO_4+MgO+Mg(CrO_2)_2+3O$. G. Viard said that not $MgO.Cr_2O_3$ but rather $2MgO.Cr_2O_3$ and $5MgO.4Cr_2O_3$ are produced. E. Schweizer said that 100 parts of water dissolve 28·2 parts of the salt at 20°, and 34·3 parts at 60°; and M. Gröger, that the salt is not decomposed by cold water. The salt is insoluble in alcohol. S. H. C. Briggs reported that the *hexahydrate*, $K_2Mg(CrO_4)_2.6H_2O$, is formed by cooling a conc. soln. to −10°. The lemon-yellow crystals can be washed with alcohol and ether. When dried in air at 8°–10°, the salt loses 4 mols. of water. G. N. Wyrouboff said that the hexahydrate is formed by evaporating the soln. below 1·8°. C. von Hauer could not make the hexahydrate. A. Duffour found that the hexahydrate can be obtained if the two chromates are dissolved separately in equimolar proportions in two and a half times their weight of warm water, and the soln. are mixed, filtered, and left to evaporate at a temp. not exceeding 15°. After several days, the hexahydrate separates in tabular crystals, which should be removed at once. The crystals after five or six hours begin to change slowly into the dihydrate. This dehydration is far more rapid at 120° but always stops at the dihydrate. The hexahydrate is thus known only in a metastable state even 10°. The crystals are monoclinic and have the axial ratios $a:b:c=0.7521:1:0.4984$, and $\beta=103° 54'$. Monoclinic crystals of the hexahydrate, in solid soln. with the hexahydrated potassium magnesium sulphate, can be obtained by the evaporation at 20° of a soln. with 3 mols of the complex sulphate to one mol of the complex chromate. A. Duffour studied the triclinic crystals of solid soln. of hexahydrated potassium magnesium chromate and sulphate.

S. H. C. Briggs prepared **rubidium magnesium chromate,** $Rb_2CrO_4.MgCrO_4.6H_2O$, by a process analogous to that used for the potassium salt. The lemon-yellow crystals are stable in air. T. V. Barker also prepared this salt and found that the axial ratios of the monoclinic crystals are $a:b:c=0.7558:1:0.4950$, and $\beta=104° 55'$; M. W. Porter gave 0·7540 : 1 : 0·4960 and $\beta=104° 52'$. A. E. H. Tutton and M. W. Porter gave for the optic axial angle :

	Li-	C-	Na-	Tl-	Cd-light
$2V$ . .	88° 27′	88° 4′	86° 33′	84° 31′	83° 15′

They also gave for the topic axial ratios $\chi:\psi:\omega=6.3403:8.4246:4.1727$; and the sp. gr. 2·466 at 20°/4°. M. W. Porter gave 2·463 at about 16°, and the mol. vol. at 20° is 215·48 ; F. A. Henglein gave 217·0. M. W. Porter found that the indices of refraction are $\alpha=1.6363$, $\beta=1.6371$, and $\gamma=1.6528$. A. E. H. Tutton and M. W. Porter found for the indices of refraction :

	Li-	C-	Na-	Tl-	Cd-light
α . .	1·6105	1·6118	1·6217	1·6342	1·6426
β . .	1·6208	1·6221	1·6330	1·6466	1·6561
γ . .	1·6310	1·6326	1·6435	1·6517	1·6672

The refractive indices, α, β, and γ, diminish respectively by 0·0019, 0·0024, and 0·0025 on raising the temp. to 80°. M. W. Porter examined the optical properties of isomorphous mixtures of ammonium and rubidium magnesium chromates. M. W. Porter showed that the ammonium and rubidium magnesium chromates are completely isomorphous. Selecting some of the observed data for the isomorphous mixtures containing 0, 35·35, 74·05, and 100 per cent. of the ammonium salt, the axial ratios were 0·7540 : 1 : 0·4960, and $\beta=104° 52'$; 0·7526 : 1 : 0·4928, and $\beta=105° 23'$; 0·7522 : 1 : 0·4931, and $\beta=105° 47'$; and 0·7517 : 1 : 0·4935, and $\beta=106° 9'$ respectively ; the sp. gr., 2·463, 2·211, 1·998, and 1·835 respectively ; and the indices of refraction $\alpha=1.6216$, $\beta=1.6330$, and $\gamma=1.6439$; $\alpha=1.6268$, $\beta=1.6371$, and $\gamma=1.6468$; $\alpha=1.6330$, $\beta=1.6368$, and $\gamma=1.6493$; and $\alpha=1.6363$, $\beta=1.6371$, and $\gamma=1.6538$ respectively. S. H. C. Briggs prepared **cæsium magnesium chromate,** $Cs_2Mg(CrO_4)_2.6H_2O$, by the method employed for the potassium salt. The cæsium salt is rather more stable than the rubidium salt. T. V. Barker gave for the axial ratios of the monoclinic crystals $a:b:c=0.7420:1:0.4886$, and $\beta=106° 7'$. A. E. H. Tutton and M. W. Porter gave for the optic axial angles :

	Li-	C-	Na-	Tl-	Cd-light
$2E$ . .	131° 3′	131° 27′	132° 55′	133° 22′	—
$2V_a$ . .	67° 9′	67° 7′	67° 3′	66° 33′	65° 57′

The topic axial ratios are $\chi:\psi:\omega=6.4441:8.6718:4.2388$; the sp. gr. is 2·747 at 20°/4° ; and the mol. vol. 227·62 ; F. A. Henglein gave 229·2. A. E. H. Tutton and M. W. Porter found the indices of refraction to be :

	Li-	C-	Na-	Tl-	Cd-light
α . .	1·6257	1·6271	1·6369	1·6493	1·6578
β . .	1·6310	1·6324	1·6425	1·6552	1·6640
γ . .	1·6424	1·6438	1·6547	1·6683	1·6778

A rise of temp. to 80° results in the reduction of the indices by about 0·0026.

Normal **zinc chromate,** $ZnCrO_4$, is not easy to prepare, for, if a large proportion of water be present, a basic salt is formed ; and if very conc. soln. are employed at a high temp., oxygen may be evolved. J. Milbauer[15] said that there is a 72 per cent. conversion to chromate when a mixture of chromic oxide and zinc oxide or carbonate is heated to 480° in oxygen at 12 atm. press. S. H. C. Briggs did not succeed in preparing the normal chromate in a non-aqueous solvent. J. Schulze obtained normal zinc chromate by heating the dichromate with zinc hydroxide in a sealed tube to 200°; and S. H. C. Briggs recommended heating for 3 hrs. at 220° in a sealed tube a mixture of 4·5 grms. CrO_3, 4·5 grms. zinc carbonate with 70 per cent. ZnO, and 5 c.c. of water. According to M. Gröger, by shaking zinc oxide with a soln. of chromic acid, in different proportions, and after a few days, determining the compositions of the filtrate, and precipitate, the composition of the soln. is found to vary continuously, Fig. 49, but the composition of the solid phase shows discontinuities, Fig. 49; if the concentrations of the soln. be expressed in mols per litre, the solid phases correspond with

CrO . .	0·00010	0·1140	0·6660	1·92	4·62
ZnO_3 .	0·00016	0·0720	0·3720	1·03	2·41
Solid.	$4ZnO.CrO_3.3H_2O$	$3ZnO.CrO_3.2H_2O$	$2ZnO.CrO_3.1\frac{1}{2}H_2O$	$3ZnO.2CrO_3$	

Beyond the limit $CrO_3 : ZnO = 4·62 : 2·41$, the solid phase is the *monohydrate*, $ZnCrO_4.H_2O$. The soln. also contained some zinc mono- and di-chromates. All the solids were crystalline excepting the 3 : 2 : 1 compound. The monohydrated monochromate did not lose water at 125°; and it was not found possible to convert it into the insoluble, anhydrous salt.

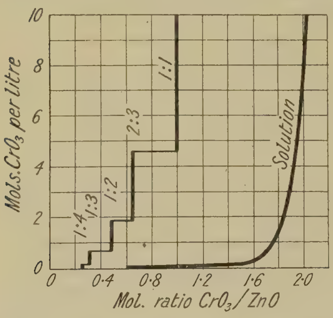

FIG. 49.—Equilibrium Conditions in the System: $ZnO–CrO_3–H_2O$ at 25°.

According to J. Schulze, normal zinc chromate furnishes microscopic, lemon-yellow, prismatic crystals, which are insoluble in water, easily soluble in acids, and are decomposed by boiling with water to form soluble dichromate and an insoluble basic chromate. M. Gröger's observations on the action of water on the monohydrate are summarized in Fig. 49. H. S. Taylor and G. I. Lavin studied the action of activated hydrogen on the chromate. E. C. Franklin said that zinc chromate is insoluble in liquid ammonia; and A. Naumann, that it is insoluble in acetone. M. Gröger said that the product of the action of zinc chloride on an excess of ammonium chromate is probably **zinc amminochromate,** $ZnCrO_4.NH_3.H_2O$. This *monohydrate* is decomposed by water; and forms zinc chromate when heated giving off nitrogen and water. L. Bieler prepared the *trihydrate* of **zinc tetramminochromate,** $ZnCrO_4.4NH_3.3H_2O$, by dissolving the basic salt in the smallest amount of aq. ammonia, and adding to the filtrate 2 or 3 times its vol. of absolute alcohol. The crystals are then dissolved in aq. ammonia, some ammonium chloride is added, and the salt again precipitated with alcohol. The rhombic plates rapidly effloresce forming a yellow powder. The salt is freely soluble in aq. ammonia, and in dil. acids; but it is decomposed by water with the separation of a basic salt. F. J. Malaguti and M. Sarzeau obtained the *pentahydrate*, $ZnCrO_4.4NH_3.5H_2O$, by allowing a basic salt to stand for 12 hrs. in a closed flask with sat. aq. ammonia. The salt is precipitated from the clear soln. by adding alcohol. The yellow cubes are decomposed by water; they are soluble in aq. ammonia; and insoluble in alcohol and ether. By mixing the 4 : 1 : 5 basic chromate with an excess of aq. ammonia, and adding alcohol, F. J. Malaguti and M. Sarzeau obtained yellow masses of acicular crystals of **zinc decamminochromate,** $2ZnO.3CrO_3.10NH_3.10H_2O$.

A number of basic salts has been reported; and a number of these, of indefinite composition, forms the so-called *zinc yellow, zinc chrome, Zinkgelb, jaune de zinc,* or *yellow ultramarine* which is employed as a pigment. T. Thomson prepared the colour in 1825; and W. A. Lampadius, in 1829. C. O. Weber prepared a bright yellow, flocculent powder by treating a soln. of zinc sulphate and sodium carbonate with potassium chromate. Its composition approximated $4ZnO.3CrO_3.nH_2O$. M. Prud'homme and F. Binder obtained a basic salt by heating zinc hydroxide with a soln. of potassium chromate and dichromate. The zinc yellows have been discussed by L. Bock, J. G. Gentele, G. Zerr and G. Rübencamp, F. Rose, S. Tschelnitz, etc. The colour was discussed by W. Ackroyd. The conditions of equilibrium of the basic salts are indicated in Fig. 49. M. Gröger, and B. Skormin obtained **zinc trioxychromate,** $4ZnO.CrO_3.3H_2O$, as a *trihydrate,* by mixing soln. of zinc chloride and sodium chromate at ordinary temp.; by treating the basic potassium or ammonium zinc chromates with hot water; and by the action of chromic acid on zinc oxide in accord with the conditions indicated in Fig. 49. J. Prüssen and H. Philippona obtained it by boiling the precipitate obtained by mixing zinc sulphate and potassium chromate soln. with much water for a long time. F. J. Malaguti and M. Sarzeau said that the *pentahydrate* is formed when zinc carbonate is treated with a soln. of chromic acid. H. Kopp added that if the chromic acid contains sulphuric acid as impurity, the precipitate will be contaminated with basic zinc sulphate. M. Gröger obtained **zinc dioxychromate,** $3ZnO.CrO_3.2H_2O$, by the action of chromic acid on zinc oxide in accord with the conditions indicated in Fig. 49. M. Gröger, and B. Skormin likewise prepared **zinc oxychromate,** $2ZnO.CrO_3.1\frac{1}{2}H_2O$. The *hemitrihydrate* was also prepared by T. Thomson, A. Bensch, and J. Prüssen and H. Philippona by the action of a soln. of zinc sulphate on one of potassium chromate. L. Vanino and F. Ziegler added a sat. soln. of chromic acid to a mol. eq. of zinc oxide suspended in water, constantly agitated. The zinc oxide passed into soln. with a rise of temp. After a time an orange or brownish-yellow product separated approximating $ZnO.ZnCrO_4.nH_2O$. S. H. C. Briggs obtained the *monohydrate* as a yellow, crystalline powder by heating for 3 hrs. in a sealed tube a mixture of 4 grms. chromium trioxide, 3 grms. of zinc oxide, and 20 grms. of water. M. Gröger also prepared **zinc oxybischromate,** $3ZnO.2CrO_3.H_2O$, by the action of chromic acid on zinc oxide in accord with the conditions indicated in Fig. 49.

It is doubtful if the **potassium zinc chromates** or the **ammonium zinc chromates** have been prepared. The products which have been reported may be adsorption products of the basic salts. M. Gröger reported products with the mol. ratios $K_2O : ZnO : CrO_3 : H_2O = 1:5:4:6$; $1:4:4:3$; and $1:1:2:2$. L. Vanino and F. Ziegler found that on mixing a sat. soln. of potassium dichromate at 100° with zinc sulphate soln. sat. at 39°, so that the ratio $CrO_3 : ZnO$ is $1:1$, or by pouring one soln. into the other, in either case, a deep yellow precipitate is formed; which after filtering and washing approximates **potassium zinc trioxybischromate,** $2K_2O.3ZnO.2ZnCrO_4$. It is supposed that the zinc chromate first formed hydrolyzes when washed with water, forming this basic chromate or a mixture of basic chromates. He showed that the action of an excess of zinc chloride in an aq. soln. of N- or $3N$-K_2CrO_4 leads to the formation of a yellow, granular precipitate, which has the composition $4ZnO.K_2O.4CrO_3.3H_2O$. By repeated treatment with hot water, this is converted into the insoluble basic zinc chromate, $ZnCrO_4.3Zn(OH)_2$, which is a dark yellow powder. When fused, the zinc potassium chromate evolves oxygen, the residue consisting of potassium chromate and insoluble violet zinc chromite, $8ZnO.3Cr_2O_3$. The proportion of potassium, and, to a less extent, that of chromium, is increased by the use of an excess of the potassium chromate; with N-soln., the precipitate has the mol. composition $ZnO.0{\cdot}394K_2O.1{\cdot}094CrO_3$; with $3N$-soln., $ZnO.0{\cdot}486K_2O.1{\cdot}222CrO_3$. When treated with hot water, these precipitates yield the foregoing basic zinc chromate. These precipitates are of a deeper yellow than that formed in presence of excess of zinc salt, but after prolonged contact (2 weeks) with the mother-liquor they assume the colour and composition of the latter. The action of zinc chloride on sodium chromate leads to the formation of basic zinc chromate, $ZnCrO_4.3Zn(OH)_2$, which is obtained as a horny mass. Ammonium chromate and excess of zinc chloride give rise to a dark yellow, granular precipitate, $ZnO.0{\cdot}279(NH_4)_2O.0{\cdot}822CrO_3$, which is possibly a mixture, and is decomposed by cold water. The orange-yellow precipitate, formed by the action of an excess of ammonium chromate on zinc chloride, is stable to water or its mother-liquor and has the composition $(NH_4)_2CrO_4.ZnCrO_4.Zn(OH)_2$. When strongly heated, it decomposes suddenly, evolving nitrogen and water vapour; the residue is a powder consisting of zinc oxide and chromite, $2ZnO.Cr_2O_3$. These salts were discussed by J. J. Berzelius, C. Freese, J. Prüssen and H. Philippona, C. O. Weber, B. Skormin, and L. Bock. According to S. H. C. Briggs, **ammonium zinc diamminobischromate,** $(NH_4)_2.Zn(CrO_4)_2.2NH_3$, is formed in lemon-yellow crystals by adding an excess of ammonium chloride or nitrate to a soln. of 10 grms. of zinc hydroxide in 20 grms. of chromium trioxide in a little water and all diluted to 200 c.c. M. Gröger obtained it in prismatic crystals by the action of ammonium chromate on zinc chloride in the presence of a large excess of ammonia. M. Gröger also reported **ammonium zinc triamminosexichromate,** $(NH_4)_4Zn_4(CrO_4)_6.3NH_3$, in orange-yellow crystals, by dropping 10 c.c. of $2M$-$ZnCl_2$ into 50 c.c. of a cold, sat. soln. of ammonium chromate.

J. Schulze prepared normal **cadmium chromate,** $CdCrO_4$, by heating in a sealed tube at 200°, a mixture of cadmium dichromate and cadmium hydroxide. The pale orange-coloured powder is insoluble in water, and soluble in acids. It gradually decomposes when boiled with water. S. H. C. Briggs obtained it by heating a mixture of 3·5 grms. cadmium oxide, 3·6 grms. chromium trioxide, and 20 c.c. of water in a sealed tube at 200° for 3 hrs. He said that the yellow powder consisting of prismatic crystals is insoluble in a hot, conc. soln. of cadmium sulphate. G. Viard said that the salt is very stable and begins to decompose at dull redness. When the filtrate is allowed to stand for some time, it deposits crystals of the *dihydrate*, $CdCrO_4.2H_2O$. F. J. Malaguti and M. Sarzeau prepared **cadmium tetramminochromate,** $CdCrO_4.4NH_3.3H_2O$, by the method employed for the corresponding zinc salt. By adding alcohol to the acidic soln. of the oxychromate, they obtained a crystalline precipitate of **cadmium pentamminochromate,** $2CdO.3CrO_3.5NH_3.8H_2O$. According to M. Gröger, the ammonium salt, $(NH_4)_2O.4CdO.4CrO_3.3H_2O$, can be regarded as **cadmium hemiamminochromate,** $2CdCrO_4.NH_3.2H_2O$; and when the salt $2(NH_4)_2CrO_4.2CdCrO_4.NH_3.3H_2O$ is allowed to stand in its mother-liquor, for 3 weeks, **cadmium amminochromate,** $CdCrO_4.NH_3.H_2O$, is formed.

F. J. Malaguti and M. Sarzeau prepared **cadmium trioxybischromate,** $3CdO.2CdCrO_4.8H_2O$, by treating a soln. of a cadmium salt with potassium chromate, and boiling the precipitate with oft-removed water until the colour no longer changes. The orange-yellow powder is very slightly soluble in water. C. Freese reported **cadmium oxychromate,** $CdO.CdCrO_4.H_2O$, to be formed from boiling soln. of cadmium sulphate and potassium chromate. Only when a large excess of chromate is present is the product free from acid. C. Freese suggested that the trioxybischromate is really this salt; while B. Skormin obtained a product $4CdO.3CdCrO_4$ with 4·5 to $6{\cdot}0H_2O$. The nature of the product, said M. Gröger, depends on the time of contact of the precipitate with boiling water. Consequently the nature of the basic salts of cadmium chromate is still *sub judice.* B. Skormin described cadmium tetroxytrischromate, $4CdO.3CdCrO_4.nH_2O$. According to F. Rose, the basic chromate has been used as a yellow pigment; but its cost limits it to fine art work.

According to M. Gröger, cadmium chloride and ammonium chromate in aq. soln. interact to form a dark yellow precipitate consisting of microscopic prisms of **ammonium cadmium dihydroxyquadrichromate,** $(NH_4)_2CrO_4.3CdCrO_4.Cd(OH)_2.2H_2O$. The action of hot water on this precipitate is to convert it into a basic cadmium chromate; and when heated, the salt leaves a green residue—possibly cadmium chromite. If 10 c.c. of a soln. of cadmium chloride be dropped into 50 c.c. of a soln. of ammonium chromate, with constant stirring, deep yellow, microscopic prisms are precipitated. The composition corresponds with **ammonium cadmium amminoquadrichromate,** $2(NH_4)_2CrO_4.2CdCrO_4.NH_3.3H_2O$. S. H. C. Briggs obtained **ammonium cadmium diamminochromate,** $(NH_4)_2CrO_4.CdCrO_4.2NH_3$, by dissolving 26 grms. of chromium trioxide and 13 grms. of cadmium oxide in a little water, diluting the soln. to 200 c.c. and adding ammonia so long as the soln. remained clear. The filtrate is allowed to stand for 2 or 3 days. The yellow crystals decompose suddenly when heated to 280°–290°. The **potassium cadmium chromates** resemble the corresponding zinc salts. M. Gröger reported products with the mol. ratios $K_2O : CdO : CrO_3 : H_2O = 1 : 7 : 5 : 3$; $1 : 4 : 4 : 3$; $1 : 3 : 2 : 3$; $1 : 1 : 2 : 2$; and $1 : 1 : 4 : 2$. G. Krüss and O. Unger also prepared the $1 : 1 : 4 : 2$ complex; and B. Skormin, $1 : 7 : 5 : 3$. M. Gröger observed that on mixing aq. soln. of potassium chromate and pure cadmium chloride, a canary-yellow, granular precipitate is formed having the composition $K_2CrO_4.3CdCrO_4.Cd(OH)_2.2H_2O$. Contrary to K. Preis and B. Rayman's statement, this same precipitate is formed by the action of cadmium sulphate and potassium chromate. Cadmium potassium chromate is more stable to boiling water than is zinc potassium chromate; but is finally converted into a lemon-yellow powder, 84·53 per cent. of which is cadmium chromate. On mixing aq. soln. of cadmium chloride and sodium chromate, a yellow, flocculent precipitate is formed which rapidly becomes granular; it is a basic cadmium chromate which easily loses chromic acid when washed with water and absorbs carbon dioxide when exposed to air. When equal vols. of cadmium chloride and sodium chromate soln. are mixed hot and boiled for three days, during which period the precipitate formed is washed twenty-four times, the residue obtained has the mol. proportions $CdO : 0{\cdot}342CrO_3 : 1{\cdot}428H_2O$.

The early workers—L. N. Vauquelin,[16] C. M. Marx, S. M. Godon de St. Menin, etc.—prepared a basic mercurous chromate by treating a soln. of mercurous nitrate with potassium chromate. The presence of nitrous acid prevents the precipitation by reducing chromic acid to chromic oxide. If an excess of nitric acid be present, part of the chromic acid forms mercuric oxide and chromic nitrate and the liquid becomes amethyst-blue, but, on adding more mercurous nitrate, the whole of the chromium is precipitated as mercurous chromate. The same product is obtained whether the soln. be hot or cold, and, added P. and M. M. Richter, statements to the contrary are based on the use of mercurous nitrate contaminated with nitrite. The analyses of L. Gmelin, F. Fichter and G. Oesterheld, and S. M. Godon de St. Menin agree with the assumption that the basic salt—**mercurous oxytrischromate,** $Hg_2O.3Hg_2CrO_4$—is formed. C. Freese, and F. Fichter and G. Oesterheld also obtained it by the hydrolysis of mercurous chromate. The bright red powder turns black when exposed to light; and at a red-heat it is decomposed into chromic oxide, oxygen, and mercury. H. Rose said that it dissolves very sparingly in cold water, but freely in boiling water to form a mercuric salt. A. A. Hayes said that hydrochloric acid converts it into mercurous chloride and chromic acid; ammonia converts it into a black powder which, together with the mercurous oxide, contains about half the chromium as chromic oxide. R. H. Brett said that it is slightly soluble in aq. soln. of ammonium chloride or nitrate. A. A. Hayes added that it is slightly soluble in nitric acid. S. Darby found that basic mercurous chromate is transformed into normal **mercurous chromate,** Hg_2CrO_4, by boiling it with nitric acid; and F. Fichter and G. Oesterheld obtained it by dissolving basic mercurous chromate in boiling $5N$-HNO_3, and cooling; and also by treating a normal soln. of mercurous nitrate with potassium chromate. C. Freese treated an excess of a soln. of mercurous nitrate with potassium dichromate, and washed the product with dil. nitric acid; L. Schulerud added that if twice the proportion of mercurous nitrate be not present, some dichromate is formed. S. Darby found that a complex salt is produced when equimolar parts of potassium dichromate and mercury cyanide are mixed in soln. and enough nitric acid added to the boiling soln. to dissolve the precipitate; on cooling, mercurous chromate is deposited as a crystalline powder. J. A. Atanasiu found that in the electrometric titration of soln. of mercurous nitrate and potassium chromate there is a break corresponding with the formation of mercurous dichromate. Mercurous chromate may form red, rhombic plates, or it may appear as a brown, amorphous precipitate which soon becomes red, and crystalline. F. Fichter and G. Oesterheld said that it should be precipitated from ice-cold soln. since hydrolysis occurs at higher temp., and basic salts are formed. O. D. Swett said that nitric acid is a good solvent for this chromate. According to S. Darby, hydrochloric acid precipitates mercury quantitatively from the soln. of the salt in nitric acid; and ammonia, or potassium hydroxide gives black precipitates. P. and M. M. Richter found that potassium bromide, iodide, and cyanide react similarly; the iodide, for example, precipitates green mercurous iodide which, with more potassium iodide, forms mercury and mercuric iodide, and thus dissolves as $KHgI_3$; with potassium cyanide, the complex $2K_2CrO_4.3HgCy_2$ is formed. F. Fichter and G. Oesterheld said that the salt is less soluble in a soln. of potassium chromate than it is in water. A. Naumann found that the salt is insoluble in acetone; and H. Rose, that it is slightly soluble in dil. nitric acid, very soluble in conc. nitric acid, soluble in a soln. of potassium cyanide, and insoluble in a soln. of mercurous nitrate.

F. Fichter and G. Oesterheld observed that the hydrolysis of normal mercurous chromate furnishes the oxytrischromate (*q.v.*), and subsequently **mercurous oxybischromate,** $Hg_2O.2Hg_2CrO_4$. This salt is formed when freshly precipitated mercurous chromate is boiled with water so long as chromic acid passes into soln. If precipitated mercurous chromate be allowed to stand under the mother-liquid, containing an excess of mercurous nitrate for 7 days, or if it be boiled with mother-liquid for 4 hrs., dark red microscopic needles of the oxybischromate are formed. P. and M. M. Richter obtained **mercurous dioxychromate,** $2Hg_2O.Hg_2CrO_4$, by the action of alkalies on mercurous chromate. This salt forms black crystals, which when dried at a high enough temp. becomes dark green or brownish-black owing to the loss of a little mercury—*vide infra*, oxydimercuriammonium chromate; for the properties of these basic chromates, *vide supra*, mercurous oxytrichromate.

M. Gröger reported **potassium mercurous chromate,** $K_2CrO_4.Hg_2CrO_4$, to be formed by the action of a soln. of mercurous nitrate, containing as little free nitric acid as possible, on a sat. soln. of potassium chromate. After shaking for a couple of weeks, the solid is separated by a suction filter, and dried on a porous tile. The brownish-yellow product decomposes when melted; and when treated with water it furnishes basic mercurous chromate.

According to A. Geuther, and A. J. Cox, if equimolar parts of chromium trioxide and yellow mercuric oxide be boiled with water, red crystals of **mercuric chromate,** $HgCrO_4$, are formed. The dark garnet-red, rhombic prisms become still darker when heated, but they lose no weight at 135°; at a red-heat, the salt decomposes yielding mercury, oxygen, and chromic oxide. The salt is hydrolyzed by cold water, and with hot water, a residue $7HgO.2CrO_3$ is formed; the hydrolysis can proceed further until finally mercuric oxide remains. If the conc. of the chromic acid be less than 0·46 mol CrO_3 per litre, the normal chromate is unstable—Fig. 50. Cold conc. nitric acid transforms the salt into $7HgO.2CrO_3$; moderately conc. nitric and sulphuric acids also form $7HgO.2CrO_3$. The salt is completely soluble in hydrochloric acid, and from this soln., alkali-lye precipitates mercuric oxide. M. Gröger obtained **mercuric diamminochromate,** $HgCrO_4.2NH_3.H_2O$, by dropping a soln. of 8·64 grms. of mercuric oxide in 6 c.c. of nitric acid of sp. gr. 1·41, and diluted to 20 c.c. into 50 c.c. of a soln. of 2 mols. of ammonium chromate. A. Naumann said that the mercuric chromate is insoluble in ethyl acetate and in acetone.

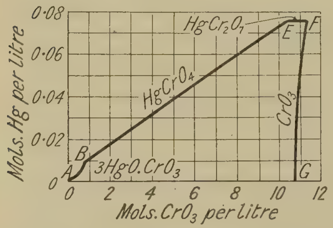

Fig. 50.—Conditions of Equilibrium of Mercuric Chromates at 25°.

A. J. Cox studied the ternary system: $HgO–CrO_3–H_2O$ at 25°, and found that under these conditions only one basic salt is formed. The invariant points, *A*, *B*, *E*, *F*, *G*, Fig. 50, are indicated in Table IV. where concentrations are expressed

TABLE IV.—INVARIANT POINTS IN THE SYSTEM $HgO–CrO_3–H_2O$ AT 25°.

N. A. E. Millon boiled yellow mercuric oxide with a soln. of potassium dichromate and obtained **mercuric dioxychromate,** $2HgO.HgCrO_4$, or $3HgO.CrO_3$. B. Skormin obtained the same product from freshly precipitated yellow mercuric oxide and an excess of a soln. of potassium dichromate. N. A. E. Millon, B. Skormin, C. Freese, and A. J. Cox also obtained it by treating a soln. of mercuric nitrate with potassium dichromate or chromate. The conditions of equilibrium are illustrated by Fig. 51. N. A. E. Millon found that the same product is obtained with mercuric chloride, but A. Caillot could not prepare it with mercuric bromide. A. J. Cox, and A. Geuther obtained it by the hydrolysis of mercuric chromate; and A. Geuther, by pouring a cold solution of mercuric carbonate in conc. nitric acid into cold water—the precipitate is at first yellow, but soon becomes scarlet-red. B. Skormin also prepared this salt. A. J. Cox showed that the minimum conc. of acid in which the salt is stable is 0·00026N-HNO_3 at 50°. J. L. Gay Lussac and L. J. Thénard found that mercuric chromate is decomposed with incandescence when heated with potassium.

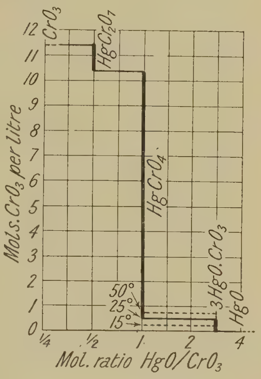

FIG. 51. — Conditions of Equilibrium in the System: $HgO–CrO_3–H_2O$ at 25°.

Several other basic salts have been reported; thus, E. Jäger and G. Krüss, and F. W. Clarke and D. Stern reported $6HgO.CrO_3$, but neither B. Skormin, nor A. J. Cox could verify its existence; E. Jäger and G. Krüss also reported $5HgO.CrO_3$, but A. J. Cox could not confirm the result; N. A. E. Millon, and F. W. Clarke and D. Stern, $4HgO.CrO_3$, but neither A. J. Cox, nor B. Skormin could accept the evidence; M. Gröger stated that this compound forms the ammino compound $3(4HgO.CrO_3).2NH_3.3H_2O$, by extraction with a soln. of ammonium chromate. A. Geuther, and F. W. Clarke and D. Stern reported $7HgO.2CrO_3$, but C. Freese, B. Skormin, and A. J. Cox were unable to verify the result; and A. Geuther reported $2HgO.CrO_3$, but A. J. Cox could not confirm the result. F. Rose mentioned the use of the basic chromates as pigments—*purple red,* or *chrome red.*

F. M. Litterscheid added ammonia to a soln. of potassium dichromate, mixed with an excess of mercuric chloride, in the cold until the liquid had an alkaline reaction; and obtained **dimercuriammonium chromate,** $(NHg_2)_2CrO_4.2H_2O$. The same product was obtained by adding an excess of ammonia to a cold soln. of mercuric chloride, and then adding a soln. of potassium chromate or dichromate. The lemon-yellow precipitate gave off no water when heated for many hours at 100°; it is virtually insoluble in water, and in a cold 10 per cent. soln. of ammonia—free from ammonium salts. The moist salt dissolves in soln. of ammonium salts.

The moist compound is freely soluble in 10 per cent. hydrochloric acid, but if the salt has been dried it dissolves with difficulty. The dried salt is easily soluble in 25 per cent. hydrochloric acid; and is insoluble in boiling, conc. nitric or sulphuric acid, with gradual decomposition; the moist salt is more easily attacked by these acids. F. W. Clarke and D. Stern obtained what they regarded as a complex salt, *ammonium dimercuriammonium chromate.* According to E. C. Franklin, a salt of this composition can be regarded as *mercuric hydroxyimidochromate,* $(HO.Hg.NH.Hg)_2CrO_4$; or as *oxydimercuriammonium chromate,* $(NH_2.Hg.O.Hg)_2CrO_4$. F. Fichter and G. Oesterheld obtained it by the action of aq. ammonia on mercurous chromate, and said that P. and M. M. Richter were wrong in saying that the product of the action is mercurous dioxychromate; the action of alkalies furnishes a mixture of mercurous oxide, or mercuric oxide and mercury. C. Hensgen obtained this product by the action of a hot, conc. soln. of ammonium chromate on mercuric chloride, and by boiling the complex dichromate with aq. ammonia or potash-lye; C. H. Hirzel, by digesting basic oxydimercuriammonium chromate (*vide infra*) with aq. ammonia, and washing with hot water; and B. Skormin, by mixing an excess of a cold, conc. soln. of ammonium chromate with mercuric nitrate, and boiling the orange-yellow, amorphous precipitate with water until it gives no reaction for nitric acid, and is colourless. The yellow product can be represented as an amidochromate, $3HgO.Hg(NH_2)_2CrO_3$; it becomes greyish-yellow at 100°, and begins to decompose into ammonia and a basic *mercuric amidochromate,* $3HgO.Hg(NH_2)_2CrO_3$. When heated in a tube, it gives a yellowish-red sublimate and mercury; it glows brightly with sparking when heated in air; it is not decomposed by potash-lye, but with a boiled soln. ammonia is evolved; it develops ammonia when heated with a soln. of potassium iodide; and it is soluble in hydrochloric acid, but nitric and sulphuric acids have scarcely any action.

C. H. Hirzel prepared **oxydimercuriammonium mercuric oxyquadrichromate,** $HgO.3HgCrO_4(NH_2.Hg.O.Hg)_2CrO_4$. He said that a cold soln. of ammonium dichromate has no apparent action on yellow mercuric oxide; but when the mixture is boiled this salt is formed as an orange-yellow, sandy powder. C. Hensgen regarded it as a mixture of mercuric oxide or basic mercuric chromate, and ammonium oxydimercuriammonium dichromate; and E. C. Franklin represented it by the formula $3HgCrO_4.HgO.(HO.Hg.NH.Hg)_2CrO_4$. C. H. Hirzel found that when heated in a tube, the compound darkens in colour and then decomposes with a feeble detonation; or it may yield nitrous vapours, a yellow sublimate of mercury, and chromic oxide. Ammonia transforms it into lemon-yellow oxydimercuriammonium chromate; potash-lye makes the colour paler, but gives no ammonia; boiling soln. of potassium iodide or sulphide liberate the nitrogen quantitatively as ammonia; conc. nitric acid decomposes it without its passing into soln.; and it forms a reddish-yellow soln. with hydrochloric acid.

S. Löwenthal described *mercuric amidochromate,* $Hg_3NH_2(CrO_4)_2$; and M. Gröger said that *potassium mercuric chromate* is not produced by treating mercuric nitrate or chloride as in the analogous process for the mercurous salt, but rather yields a basic chromate which adsorbs potassium chromate.

A. J. Fairrie,[17] and C. W. Eliot and F. H. Storer treated a soln. of potash-alum with potassium chromate, and obtained a precipitate which after pressing, corresponded with **aluminium dioxychromate,** $Al_2O_2.CrO_4.nH_2O$. M. Siewert, and A. Maus also dissolved aluminium hydroxide in a soln. of chromic acid, and on evaporating the liquid, obtained aluminium hydroxide, and an acidic soln. E. Fleischer observed that no precipitate is produced by adding potassium dichromate to a soln. of potash-alum; and when the liquid is evaporated alum first crystallizes out, and then potassium dichromate. There is here no satisfactory evidence of the formation of an aluminium chromate. L. Blanc, however, regarded the formation of the basic chromate as proved. According to M. Gröger, the addition of aq. potassium chromate to a soln. of potassium-alum precipitates basic aluminium sulphates; as the quantity of the chromate is increased, the precipitate becomes mixed with an increasing amount of chromate; when the alum and potassium chromate are in the ratio $Al_2O_3 : 2CrO_3$, no precipitate is formed. On mixing soln. of aluminium chloride and potassium chromate, a yellow precipitate is formed which has the composition $2Al_2O_3.CrO_3.6H_2O$; the precipitation of the aluminium is not complete until 3 mols of potassium chromate have been added for each mol of aluminium chloride. Soln. made by dissolving aluminium hydroxide in chromic acid always contain Al_2O_3 and CrO_3 in the proportion of 1 : 1·4 to 1·45; from this soln., the insoluble basic chromate mentioned above separates on keeping. No indication was observed of the formation of the compound $Al_2O_3.CrO_3.7H_2O$, described by A. J. Fairrie. N. A. Orloff said that aluminium chromate, like beryllium chromate, is hydrolyzed by water without forming any definite basic salt; and L. Petrik represented the reaction: $Al_2(SO_4)_3+3K_2CrO_4+3H_2O=Al_2(OH)_6+3CrO_3+3H_2SO_4$—*vide supra,* the colour of chromic oxide. S. H. C. Briggs added a soln. of 4 grms. of hydrated aluminium chloride in 25 c.c. of water to a soln. of 15 grms. of sodium chromate in 30 c.c. of water, and heated the mixture for an hour on the water-bath. The filtered precipitate was washed with a little water, and dried in vacuo. A mixture of 2 grms. of chromic trioxide, 2 c.c. of water, and 1·8 grms. of the powdered product was heated in a sealed tube at 200° to 210° for 4 hrs., and the crystalline, insoluble, lemon-yellow product corresponded with **aluminium oxydichromate,** $3Al_2O_3.2CrO_3.6H_2O$, or $Al_2O_3.2(AlO)_2CrO_4.6H_2O$.

According to R. E. Meyer,[18] and C. Winkler, a soln. of a neutral salt of indium gives an insoluble precipitate of an **indium chromate** when treated with an alkali chromate. A soln. of indium sesquioxide in aq. chromic acid, does not crystallize when evaporated, or when allowed to stand in a desiccator. Only a viscid syrup is produced. W. Crookes[19] observed that **thallous chromate,** Tl_2CrO_4, is precipitated when a soln. of a neutral thallous salt is treated with potassium chromate; and also by digesting thallous dichromate with ammonia. E. Carstanjen obtained it from a soln. of thallous carbonate in aq. chromic acid. G. Canneri observed that M. Gröger's method for basic lead chromates yields with thallous salts, only the normal chromate. The action of dil. acid on thallous chromate yields thallous dichromate, but if a quantity of sulphuric acid insufficient to dissolve the chromate is employed and the boiling soln. is filtered and conc. **thallous hydrochromate,** $TlHCrO_4.Tl_2CrO_4$, in cinnabar-red crystals, and often in cruciform twins, is formed. Thallous chromate darkens when heated, and then melts without decomposition. At a higher temp. the salt decomposes. J. W. Retgers said that the crystals are probably not isomorphous with potassium chromate or thallous sulphate. According to G. Canneri, the e.m.f. of the electrode, mercury amalgam against a saturated thallous chromate soln. varies continuously with the temp., the curve exhibiting no characteristic point corresponding with the change in colour which thallous chromate crystals undergo when heated at 60°. Similarly the conductivity of sat. thallous chromate shows no sudden variation between 25° and 90°. The pale yellow or lemon-yellow amorphous precipitate is slightly soluble in water. E. Rupp and M. Zimmer said that 100 parts of water at 60° dissolve 0·03 part of thallous chromate; and P. E. Browning and G. P. Hutchins said that 100 grms. of water at 100° dissolve 0·2 grm. E. Carstanjen observed that it is attacked by dil. hydrochloric acid; and W. Crookes found that it is dissolved by moderately conc. boiling hydrochloric acid, and on cooling vermilion-red crystals separate—probably the trichromate. E. Carstanjen added that with conc. hydrochloric acid, thallous chloride is separated, and a green soln. is formed. W. Crookes also observed the formation of thallium chloride by the action of conc. hydrochloric acid. E. Carstanjen found that dil. sulphuric acid attacks thallous chromate slowly in the cold, and when the acid is heated, E. Willm said that the di- or tri-chromate is formed. With conc. sulphuric acid, violet thallium chrome-alum separates out. E. Carstanjen observed that dil. nitric acid, as well as conc. acetic acid, do not dissolve thallous chromate in the cold, but with boiling soln., a little chromate is dissolved. It also behaves similarly towards aq. soln. of ammonia and sodium carbonate. M. Lachaud and C. Lepierre found that a litre of boiling N-KOH dissolves 3·5 grms. of thallous chromate, and on cooling, almost all separates out in six-sided pyramidal crystals. A soln. of potash-lye of sp. gr. 1·3 dissolves 18 grms. of chromate per litre. Molten potassium hydroxide converts it into thallic oxide. When thallous and potassium chromates are melted with potassium nitrate, **potassium thallous chromate,** $KTlCrO_4$, or $K_2CrO_4.Tl_2CrO_4$, is formed. M. Hebberling, and W. Strecker observed that reddish-yellow or brown precipitates are obtained when soln. of thallic salts are treated with soluble chromates or dichromates. The result is **thallic chromate.** According to G. Canneri, thallic chromate may be obtained pure as a golden yellow, crystalline powder by dissolving freshly-precipitated thallic oxide in excess of chromic anhydride soln. According to L. F. Hawley, **potassium thallic chromate,** $KTl(CrO_4)_2.2H_2O$, is obtained by adding potassium hydroxide to a soln. of thallic hydroxide in chromic acid. The yellow salt is rapidly hydrolyzed by water unless a large excess of chromic acid is present.

L. Haber[20] observed no precipitation occurs when cerium, lanthanum, and didymium salts are boiled with chromic acid, or with potassium or sodium dichromate, but a basic salt is precipitated when thorium or zirconium salts are similarly treated. J. F. John, and A. Beringer found that a soln. of cerous carbonate in aq. chromic acid slowly deposits **cerous chromate** as a yellow powder, and when the mother-liquor is evaporated, crystals of an acid salt are formed. According to S. Jolin, soln. of cerous salts also give precipitates of basic cerous chromates when treated with soln. of potassium chromate or dichromate. F. Zambonini and G. Carobbi found that when an intimate mixture of cerous chloride and potassium chromate is heated to 1000°, chromic oxide and cerium dioxide are formed. M. M. Pattison and J. Clarke found that when the chromates obtained by evaporating to dryness a soln. of the mixed oxides of cerium, didymium, and lanthanum in chromic acid, are heated to about 110°, only the cerium chromate is decomposed to form an insoluble powder, while the chromates of didymium and lanthanum remain unchanged. A. Brauell, and L. M. Dennis and B. Dales founded analytical processes on this reaction; G. Krüss and A. Loose, and W. Muthmann and C. R. Böhm found that the fractional precipitation by potassium chromate of the ceria earths proceeds in the order: La, Pr, Nd, Sm; and of the yttria earths, in the order: Tb, Yb, Er, Y, Gd. Processes of separation have been devised—by J. E. Egan and C. W. Balke, B. S. Hopkins and C. W. Balke, H. Moissan and A. Étard, C. R. Böhm, W. Muthmann and C. R. Böhm, L. M. Dennis and B. Dales, R. J. Meyer and J. Wuorinen, H. C. Holden and C. James, and C. James—based on this reaction—*vide* **5**. 38, 6. According to F. Frerichs and F. Smith, a soln. of lanthanum sulphate and potassium chromate gives a precipitate consisting of **lanthanum chromate,** $La_2(CrO_4)_3.8H_2O$. Lanthanum chromate is very liable to form a sparingly soluble potassium complex salt so that P. T. Cleve said that the precipitate probably contains the complex salt. The precipitate is yellow, granular, and consists of microscopic crystals. It is sparingly soluble in cold water and freely soluble in acids. P. T. Cleve obtained the octohydrate by treating a soln. of lanthanum nitrate with potassium chromate. H. T. S. Britton also prepared the *octohydrate* of lanthanum chromate by dissolving about 2 grms. of the rare earth in the minimum amount of chromic acid soln.; diluting the liquid to 2 litres; and gradually adding $0{\cdot}1M$-K_2CrO_4. When the amount of chromic acid used was kept sufficiently low, the quantity of potassium chromate required was small, thereby causing the simple chromate alone to be precipitated, but if too great a quantity of acid had been employed a correspondingly large amount of precipitant was necessary, and this often caused the precipitation of double chromates together with varying amounts of simple chromates. The salt is a bright yellow mass of microscopic, prismatic needles. 100 grms. of water at 25° dissolve 0·020 grm. calculated as anhydrous salt. The solubility is less at higher temp. F. Zambonini and G. Carobbi obtained the anhydrous salt by heating the rare earth chloride and potassium chromate over 600°; and they obtained the *monohydrate*, $La_2(CrO_4)_3.H_2O$, by precipitation from cold soln. G. Carobbi studied the system $La_2(CrO_4)_3$–$(NH_4)_2CrO_4$–H_2O at 25°—Fig. 52. The only complex salt formed was **ammonium lanthanum hexachromate,** $La_2(CrO_4)_3.3(NH_4)_2CrO_4.5H_2O$. The study of the system is complicated by the alteration of ammonium chromate into dichromate, so that when the ammonium chromate is in excess, ammonium dichromate crystallizes out, and when lanthanum chromate is in excess, the salt $La_2(CrO_4)_3.8H_2O$ separates. H. T. S. Britton obtained **potassium lanthanum tetrachromate,** $K_2CrO_4.La_2(CrO_4)_3.6H_2O$, as indicated above. P. T. Cleve found that if an excess of potassium chromate be employed, there is formed **potassium lanthanum heptachromate,** $4K_2CrO_4.La_2(CrO_4)_3.nH_2O$. G. Carobbi studied the system $La_2(CrO_4)_3$–K_2CrO_4–H_2O at 25°, and found that the existence of the hydrated complex chromates, 1 : 1 : 2; 1 : 3 : 2; 1 : 4 : 2; 1·4 : 5 : 2; and 1 : 5 : 2, are indicated on the isothermal curve, Fig. 53. F. Frerichs and F. Smith obtained a precipitate resembling that with the lanthanum salt when a soln. of a didymium salt is treated with potassium chromate. The precipitated **didymium chromate,** $Di_2(CrO_4)_3.8H_2O$, was said by P. T. Cleve to be contaminated with a complex potassium salt which is obtained by treating a soln. of didymium nitrate with an excess of potassium chromate. H. T. S. Britton also obtained the bright yellow *octohydrate* of **praseodymium chromate,** $Pr_2(CrO_4)_3.8H_2O$, as in the case of the lanthanum salt; 100 grms. of water at 25° dissolve the eq. of 0·021 grm. of the anhydrous salt. F. Zambonini also prepared the anhydrous salt, as well as the *decahydrate*, $Pr_2(CrO_4)_3.10H_2O$, by the methods indicated in connection with the anhydrous, and the monohydrated lanthanum salts. H. T. S. Britton likewise prepared the dull yellow *octohydrate* of **neodymium chromate,** $Nd_2(CrO_4)_3.8H_2O$, with a solubility of 0·027 grm. per 100 grms. of water at 25°. E. Baur said that this salt is olive-brown; and N. A. Orloff, moss-green. As in the case of the praseodymium salt, F. Zambonini and G. Carobbi also prepared the anhydrous salt, and the decahydrate. By adding an excess of potassium chromate to the soln. of a didymium salt, P. T. Cleve obtained yellow **potassium didymium chromate,** $K_2CrO_4.Di_2(CrO_4)_3.nH_2O$. It is hydrolyzed when washed with water with the loss of potassium chromate. H. T. S. Britton obtained a mixture of a basic chromate and **potassium praseodymium chromate** by adding an excess of potassium chromate to a chromic acid soln. of praseodymia; and similarly with **potassium neodymium chromate.** H. T. S. Britton obtained the *octohydrate* of **samarium chromate,** $Sa_2(CrO_4)_3.8H_2O$, as in the case of the lanthanum salt; 100 grms. of water at 25° dissolved 0·043 grm. of the salt calculated as anhydrous. F. Zambonini and G. Carobbi prepared the anhydrous salt and the *enneahydrate*, $Sa_2(CrO_4)_3.9H_2O$, as in the case of the anhydrous and monohydrated lanthanum salts. By adding potassium chromate to a soln. of a samarium salt, P. T. Cleve obtained a yellow, crystalline precipitate of **potassium samarium chromate,** $K_2CrO_4.Sa_2(CrO_3)_3.6H_2O$. No precipitation occurs with potassium dichromate. H. T. S. Britton found that

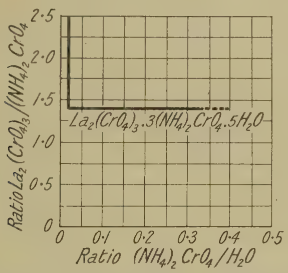

FIG. 52.—Equilibrium in the System: $La_2(CrO_4)_3$–$(NH_4)_2CrO_4$–H_2O at 25°.

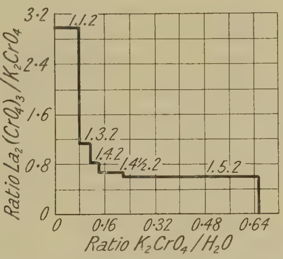

FIG. 53.—Equilibrium in the System: $La_2(CrO_4)_3$–K_2CrO_4–H_2O at 25°.

with an excess of potassium chromate the composition of the yellow flocculent precipitate varied with the composition of the precipitant; a complex salt is probably formed. The application of the phase rule is required to establish the nature of the complex salts. In general, the addition of a soln. of potassium chromate to an aq. salt soln. causes the precipitation of (*a*) in the case of lanthanum, the simple chromate if the excess of precipitant is small, (*b*) praseodymium, the simple chromate, (*c*) neodymium, a mixture of simple and basic chromates, (*d*) samarium, a basic chromate of indefinite composition. H. T. S. Britton continued: The only normal chromates which have been found hitherto belong to the cerite-group, the bases of which are believed to be among the strongest of the rare earths. Even among the members of this group there is a gradually increasing tendency to form basic chromates in the case of the weaker bases, neodymia and samaria.

G. Krüss and A. Loose, and W. Muthmann and C. R. Böhm obtained precipitates of **terbium chromate,** and of **gadolinium chromate** by adding potassium chromate to soln. of the corresponding salts. P. B. Sarder obtained the complex **potassium gadolinium chromates,** $K_2CrO_4.Gd_2(CrO_4)_3.7H_2O$, and $5K_2CrO_4.2Gd_2(CrO_4)_3.10H_2O$. G. Jantsch and A Ohl prepared **dysprosium chromate,** $Dy_2(CrO_4)_3.10H_2O$, as a sparingly soluble precipitate, by the interaction of soln. of the nitrate and of potassium chromate. The greenish-yellow, crystalline powder is soluble in water—at 25°, 100 c.c. of the soln. contain 1·0002 grms. of salt. When heated to 150°, the chromate loses 3·5 mols. of water; and at 150°, it decomposes. N. J. Berlin said that a basic yttrium chromate is formed when a soln. of chromic acid is sat. with yttria. The brown soln. deposits a brown powder. The salt was also obtained by O. Popp, G. Krüss and A. Loose, and W. Muthmann and C. R. Böhm. J. F. John observed that a soln. of yttrium carbonate in aq. chromic acid deposits orange-yellow crystals, of **yttrium chromate,** $Y_2(CrO_4)_3.nH_2O$, easily soluble in water. N. J. Berlin said that the spontaneous evaporation of the soln. gives yellowish-brown deliquescent crystals. P. T. Cleve obtained **potassium yttrium chromate,** $K_2CrO_4.Y_2(CrO_4)_3.nH_2O$, as a yellow, crystalline powder, by the action of potassium dichromate on yttrium carbonate. G. Krüss and A. Loose, and W. Muthmann and C. R. Böhm also prepared **erbium chromate,** and **ytterbium chromate.**

According to S. M. Godon de St. Menin,[21] when an aq. soln. of chromic acid mixed with hydrated silicic acid is evaporated, a reddish-yellow powder—silicon chromate—is formed, insoluble in water, and is not decomposed at an elevated temp. It is highly probable that no compound is formed. G. A. Quesneville, however, said that very little silicic acid is taken up by the soln., and that all the chromic acid is removed by washing. M. Blondel found that a conc. aq. soln. of chromic acid dissolves titanic acid in amounts depending on the conc., and temp. of the soln., and on the previous history of the titanic acid. When a conc. soln. containing one part of titanic oxide and 4 parts of chromium trioxide is diluted with 8 parts of water at 50° or 6 parts of water at 100°, **titanium tetroxychromate,** $3TiO_2.2CrO_3.H_2O$, or $TiO_2.2(TiO)CrO_4.H_2O$, is precipitated; with 25 parts of cold water, or 8 parts of water at 100°, **titanium trioxychromate,** $TiO_2.(TiO)CrO_4.2H_2O$, is produced; while with 50 parts of cold water or 12 parts of water at 100°, **titanium pentoxychromate,** $2TiO_2.(TiO)CrO_4.3H_2O$, is formed. On adding an eq. of ammonia to the same conc. soln. of the two oxides, $TiO_2.(TiO)CrO_4.2H_2O$ is precipitated, and the evaporation of the mother-liquor in vacuo yields hexagonal prisms of **ammonium titanium chromate,** $(NH_4)_2CrO_4.Ti(CrO_4)_2.H_2O$. All this has not yet been verified. M. Weibull found that **zirconium chromate** is precipitated when a zirconium salt soln. is treated with chromic acid or a dichromate. The flocculent, orange-red precipitate is sparingly soluble in dil. acids; and when washed with water chromic acid passes into soln. L. Haber said that the composition of the precipitate is indefinite. F. P. Venable and L. V. Giles, however, said that a definite salt $2ZrO(OH)_2.ZrOCrO_4.8H_2O$, **zirconyl tetrahydroxychromate,** is produced as a granular, yellow precipitate by dissolving zirconium hydroxide in a boiling soln. of chromic acid, diluting, and again boiling the soln. The compound obtained loses a considerable quantity of its water at 110°, but the whole of it is lost only at 200°. It is suggested that its formation occurs as follows: first, normal zirconium chromate is formed, which is immediately hydrolyzed to $ZrOCrO_4$; some of the zirconium hydroxide is partly dehydrated to give $ZrO(OH)_2$. These two substances then combine to give the yellow insoluble basic salt. According to P. Krishnamurti and B. B. Dey, the addition of a large excess of a sat. soln. of potassium dichromate to a conc. soln. of zirconium oxychloride precipitates **zirconium octohydroxychromate,** $Zr_3(OH)_8(CrO_4)_2$; with a dil. soln. of the zirconium salt, **zirconium hexahydroxychromate,** $Zr_2(OH)_6CrO_4$, is formed; and with very dil., boiling soln. of the oxychloride, and only a slight excess of dichromate, the product washed with boiling water corresponds with **zirconium decahydroxychromate,** $Zr_3(OH)_{10}CrO_4$. S. H. C. Briggs added a soln. of 7 grms. of crystalline zirconium nitrate in 50 c.c. of water to 10 grms. of potassium dichromate in 80 c.c. of water, after a day, the precipitate was filtered off, washed with a little water, and dried in vacuo, 2·5 grms. of the dried powder was heated in a sealed tube at 190° for 3½ hrs. with 6 grms. chromic trioxide, and 6 c.c. of water. The orange-red, homogeneous, insoluble, crystalline powder had the composition of **zirconium hexacosioxypentachromate,** $9ZrO_2.5CrO_3.12H_2O$, or $13ZrO_2.5Zr(CrO_4)_2.24H_2O$.

W. Muthmann and E. Baur[22] found that if a soln. of potassium chromate is dropped carefully into a boiling soln. of commercial thorium nitrate, first thorium will be precipitated completely as chromate and afterwards some rare earths begin to appear, indicated by a change in colour of the precipitate. This is the principle of E. Baur's method of separating the rare earths—*vide supra.* C. Palmer obtained **thorium chromate,** $Th(CrO_4)_2.H_2O$, by allowing a soln. of freshly precipitated thorium hydroxide in aq. chromic acid to stand for some time, or by mixing boiling soln. of a mol of thorium nitrate and 2 mols of potassium dichromate. The *monohydrate* appears as an orange-red, crystalline powder. He also prepared the *trihydrate* by evaporating in vacuo a soln. of freshly precipitated thorium hydroxide in a cold soln. of chromic acid. L. Haber prepared it as an orange-yellow, crystalline powder by boiling thorium nitrate for some time with aq. chromic acid, or better with sodium or potassium dichromate. Under similar conditions no precipitate is formed with cerium, lanthanum, or didymium salts. J. J. Berzelius said that the precipitated thorium chromate dissolves in an excess of chromic acid. The orange-yellow, rhombic plates lose their water of crystallization at 180°; and they dissolve in moderately conc. mineral acids. J. Chydenius obtained yellow crystals of the *octohydrate* by evaporating over sulphuric acid a soln. of thorium hydroxide in aq. chromic acid, or an aq. soln. of thorium chloride and chromic acid. The salt loses its combined water at 100°, and the aq. soln. does not become turbid when boiled. C. Palmer also obtained **thorium dihydroxychromate,** $Th(OH)_2CrO_4$, by mixing a soln. of a mol of thorium nitrate and one of 3 mols of potassium chromate; the precipitate first formed dissolves. The soln. furnishes golden-yellow crystals of the basic salt. According to H. T. S. Britton, if thorium hydroxide is suspended in a dil. soln. of chromic acid, it will be converted gradually into the normal chromate, the change occurring more rapidly on boiling. No basic salt of definite composition has been found. The composition varies, gradually approaching that of the normal chromate, but the conversion is complete only after long boiling. Crystals may appear to be slightly basic owing to the adsorption of normal chromate. The so-called basic thorium chromates are really mixtures of thorium hydroxide and thorium chromate. In other words, these basic chromates may be regarded as so-called adsorption compounds, or, taking into account the slight solubility of the normal thorium chromate, as having been produced by the simultaneous precipitation of both the hydroxide and the chromate. The basic chromate of C. Palmer is a special case of such a mixture. When soln. of thorium salts, to which potassium chromate has been added in quantities insufficient to give a permanent precipitate owing to the acid liberated by hydrolysis, are allowed to stand at room temp., if the conc. is sufficiently great, crystals of thorium chromate trihydrate will be deposited slowly; but deposition occurs almost immediately from the boiling soln. The solubility of thorium chromate in soln. of chromic acid at 25°, when the composition is represented in percentages by weight, is as follows:

CrO_3 .	0·033	13·09	39·49	40·23	52·60	61·38	61·84	62·78
ThO_2 .	0·044	6·52	24·22	23·04	7·91	17·65	6·27	0
	$Th(CrO_4)_2.3H_2O$			$Th(CrO_4)_2.CrO_3.3H_2O$			CrO_3	

The results are plotted in Fig. 54. The compound **thorium chromatobischromate,** $Th(CrO_4)_2.CrO_3.3H_2O$, is better represented by this formula than by $Th(Cr_2O_7)(CrO_4).3H_2O$, because it can exist in equilibrium only with highly conc. soln. of chromic acid. It is decomposed by water.

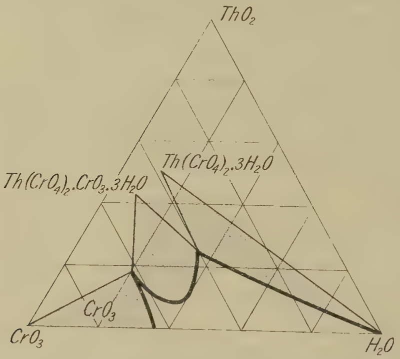

Fig. 54.—Equilibrium Diagram of the System: ThO_2–CrO_3–H_2O at 25°.

According to J. J. Berzelius,[23] when stannous chloride is added to an excess of a soln. of potassium chromate, and the liquid agitated, yellow, curdy flocks of **stannous chromate** are precipitated; but if to a soln. of stannous chloride a dil. soln. of potassium chromate be added in small portions at a time, with constant agitation, a greenish precipitate of *chromic stannate* is formed. If the soln. of the tin-salt contains free acid, no precipitate is formed, and the soln. is green. P. Grouvelle obtained a similar result. According to J. J. Berzelius, stannic chloride soln., not containing free acid, gives a yellow precipitate of **stannic chromate,** when treated with potassium chromate. The supernatant liquor acquires an orange-yellow colour in consequence of the liberation of chromic acid. The dried precipitate is brownish-yellow, and when ignited forms violet *chromic stannate.* T. Leykauf said that if stannic chromate be heated to bright redness, a violet mass is obtained which communicates to pottery glazes colours ranging from rose-red to violet. F. J. Malaguti studied the *minéral lac,* or *laque minérale,* obtained by igniting 50 parts of stannic oxide with one part of chromic oxide. The pink or crimson colour develops more easily if calcium carbonate is a constituent of the ignited mixture. This is essentially the *chrome-tin pink* pottery colour. The pink coloration is probably the colour of highly dispersed chromic oxide, and the stannic oxide acts as a mordant. Other inert oxides can be used, but stannic oxide resists attack by the pottery glaze—*vide supra,* chromic oxide. This subject was studied by H. Stein, G. Steinbrecht, C. Lauth and G. Dutailly, H. A. Seyer, A. S. Watts, R. C. Purdy and co-workers, F. Rhead, W. A. Hall, and W. A. Lethbridge.

The mineral described by M. W. Lomonosoff,[24] J. G. Lehmann, and P. S. Pallas as *nora minera plumbi;* by J. G. Wallerius, as *minera plumbi rubra;* by A. G. Werner, as *Rothes Bleierz;* and L. C. H. Macquart, as *plomb rouge,* was found by L. N. Vauquelin, in 1757, to contain a new element in the form of chromate so that R. J. Haüy called it *plomb chromaté.* J. F. L. Hausmann proposed the name *kallochrom;* W. H. Miller, *lehmannite;* F. S. Beudant, *crocoise*—from κρόκος, saffron; F. von Kobell, *crocoisite;* and A. Breithaupt, **crocoite** (*Krokoit*), which was afterwards adopted by F. von Kobell and others. Analyses of the mineral by C. H. Pfaff,[25] J. J. Berzelius, C. Bärwald, and A. Liversidge; and of artificial preparations by J. J. Berzelius, H. Golblum and G. Stoffella, M. Gröger, A. J. Cox, N. S. Manross, L. Bourgeois, M. Lachaud and C. Lepierre, and C. Lüdeking, agree that the product is **lead chromate,** $PbCrO_4$.

L. N. Vauquelin, and J. J. Berzelius obtained normal lead chromate by precipitation from a soln. of lead nitrate or acetate by the addition of potassium chromate or dichromate. The precipitate is yellow, and, according to E. F. Anthon, the colour is paler when precipitated from cold soln. than from hot soln., since the former is more or less hydrated; while L. N. Vauquelin said that a trace of potassium chromate in the precipitate darkens the colour. C. O. Weber, and M. Dullo discussed the effect of an excess of lead—*vide infra*. L. Dede and P. Bonin said that the precipitation is incomplete in acetic acid soln. if much chloride be present. Z. Karaoglanoff and B. Sagortscheff found that with lead chloride as the soluble lead salt, some $Pb_2Cl_2(CrO_4)$ is formed. The above mode of preparation, using the potassium or sodium chromates or chromic acid as precipitants, and soln. of varying degrees of concentration, were used by T. Gobel, F. G. Kidd, P. Jannasch, H. Golblum and G. Stoffella, J. Milbauer and K. Kohn, M. Fraudel, J. G. Gentele, E. Guignet, F. Rose, A. J. Cox, F. Auerbach and H. Pick, O. Meyer, M. Gröger, P. Breteau and P. Fleury, A. de Schulten, and G. Zerr and G. Rübencamp. J. Massignon and E. Watel obtained lead chromate by the action of soln. of lead salts on calcium chromate. G. N. Ridley showed that the precipitate formed on mixing aq. soln. of lead acetate and potassium dichromate is finer grained when the soln. are more dilute; but temp. has little influence on the fineness of grain. Precipitated lead chromate is amorphous. M. Lachaud and C. Lepierre found that the amorphous chromate is readily crystallized by boiling, say, 5 grms. with a soln. of 20 grms. of chromic acid in 70 grms. of water; L. Bourgeois boiled the precipitated chromate with dil. nitric acid (1 : 5 or 6), filtered the hot decanted liquid through glass-wool, and allowed it to cool slowly; he also obtained well-defined crystals by heating the chromate in a sealed tube at 150°. C. Lüdeking, and G. Cesaro allowed a soln. of lead chromate in potash-lye to stand exposed to the air. G. N. Ridley found that in alcoholic soln., precipitation is slow; and that the addition of an alcoholic soln. of potassium dichromate to a glycerol soln. of lead acetate produces only a slight turbidity—but precipitation occurs when water is added. No precipitation occurs in carbon disulphide soln.

Lead chromate was prepared by J. von Liebig, B. Legg, E. F. Anthon, M. Riot and B. Declisse, A. Scheurer, H. Hetherington and W. A. Allsebrook, and C. O. Weber by the action of soln. of the alkali chromates on lead sulphate. J. A. Atanasiu found that the electrometric titration of soln. of lead nitrate and potassium chromate gives a curve with a break corresponding with normal lead chromate. J. Milbauer and K. Kohn observed that the reaction: $PbSO_4+K_2CrO_4 \rightleftharpoons K_2SO_4+PbCrO_4$ progresses from left to right rapidly, and from right to left, slowly. The velocities of the reactions increase with temp. The equilibrium constant $K=[K_2CrO_4]/[K_2SO_4]$ is 0·000277 at 20°; 0·000365 at 40°; 0·000440 at 70°; and 0·000505 at 98·5°. No evidence of the formation of double salts was observed. The isothermal diagram has the form shown in Fig. 55, where *A* represents the solubility of potassium

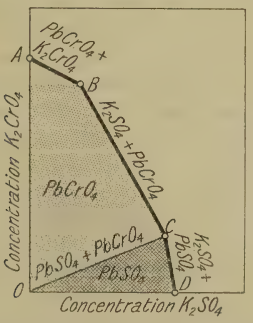

FIG. 55.—Isothermal Diagram for the System: $PbSO_4+K_2CrO_4 \rightleftharpoons K_2SO_4+PbCrO_4$.

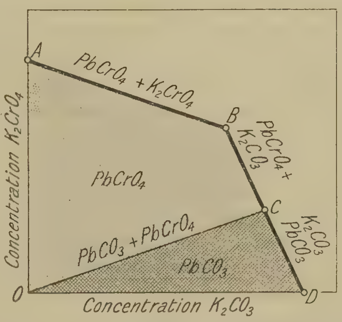

FIG. 56.—Isothermal Diagram for the System: $PbCO_3+K_2CrO_4 \rightleftharpoons K_2CO_3+PbCrO_4$.

chromate; and *D*, that of potassium sulphate. The regions of stability of the solid phases $PbCrO_4$, and $PbSO_4$ are shaded in the diagram. The curve *AB* represents a system in equilibrium with the four phases—$PbCrO_4$, K_2CrO_4, soln. and vapour; *BC*, a system in equilibrium with the four phases $PbCrO_4$, K_2SO_4, soln. and vapour; and *CD*, a system with the four phases $PbSO_4$, K_2SO_4, soln. and vapour in equilibrium. The four salts cannot exist side by side in the presence of their sat. soln. as the system would be invariant—**1**. 9, 5. At the point *C* there are six phases, $PbCrO_4$, K_2CrO_4, K_2SO_4, $PbSO_4$, soln. and vapour, in equilibrium. Adsorption is very marked at the low temp. and high concentration. It is inferred that the manufacture of chrome-yellow can be carried out from lead sulphate, and that various shades can be obtained by varying the conditions, temp., conc., and time. In the manufacture, an excess of lead acetate should be used, to secure the absence of adsorbed potassium chromate in the product, otherwise this chromate would rapidly convert the lead sulphate which is necessary for the particular shade, into lead chromate, and so the shade would be changed. J. G. Gentele's theory which explains the stability of chrome-yellow by the existence of a lead sulphatochromate is unlikely, since the present experiments make the existence of these double salts extremely doubtful.

F. Kuhlmann, C. O. Weber, and A. Winterfeld obtained lead chromate by the action of potassium chromate or dichromate on white-lead, or lead carbonate. H. Golblum and G. Stoffella studied the system: $PbCO_3+K_2CrO_4 \rightleftharpoons PbCrO_4+K_2CO_3$. The product nearly always contains a little lead carbonate. The isothermal diagram shown in Fig. 56, is analogous to that for the system indicated in the preceding diagram, Fig. 55. The mixture on the right of the equation $PbCO_3+K_2CrO_4 \rightleftharpoons PbCrO_4+K_2CO_3$, is more stable than that on the left. The equilibrium constant, $K=[K_2CO_3]/[K_2CrO_4]$, decreases with dilution on account of the disturbing effect of ionization. No compound or solid soln. of potassium chromate and lead chromate is formed, but the solubility of potassium carbonate decreases as the amount of lead carbonate in the solid residue and in soln. increases. A double compound of $K_2CO_3.PbCO_3$ appears to exist. The constant *K* at 25° is 5·46, and at 40°, 3·405. The thermal value of the reaction: $PbCO_3+K_2CrO_4=PbCrO_4+K_2CO_3$ is 5·822 Cals. If the equilibrium constant, *K*, Fig. 57, be represented by $K=Oa$, and the soln. of lead nitrate be added to a mixed soln. of potassium carbonate and chromate, when the ratio of $CO_3 \mid CrO_4$ is *greater* than *Oa*, lead carbonate alone will be precipitated until the ratio of the constituents remaining in soln. is equal to *Oa;* and conversely if the ratio be *less* than *Oa*, lead chromate alone will be precipitated. If the ratio be equal to *Oa*, and more than *Ob* of lead nitrate be added, a mixture of lead carbonate and chromate will be precipitated. On adding lead nitrate soln. to a mixed soln. of potassium chromate and carbonate, the precipitation of lead chromate or carbonate does not take place in such a way as to produce the predetermined ratio in the dissolved potassium salts. Whilst the interaction of lead carbonate and potassium chromate proceeds smoothly to an equilibrium, the interaction of lead chromate and potassium carbonate presents periodic phenomena. The curve representing the amount of potassium chromate formed oscillates with decreasing amplitude until the equilibrium is finally attained. This is attributed to the formation of a basic chromocarbonate of lead. On boiling lead chromate in potassium carbonate soln., a rhombic, ruby-red, crystalline solid is obtained with the composition: $3PbO.2CrO_3.2PbCO_3$. O. Ruff and E. Ascher studied the joint precipitation of lead and barium chromates; and lead sulphate and chromate; and O. Ruff, the X-radiograms.

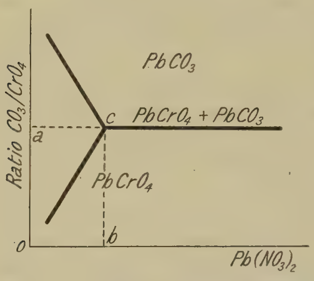

FIG. 57.—Mutual Precipitation of Lead Chromate and Carbonate.

N. S. Manross obtained crystals of lead chromate by melting lead chloride with potassium chromate, and leaching out the lead chloride, with boiling water. L. Bourgeois said that the yield is small because of the formation of the complex salt, $PbCl_2.PbCrO_4$. A better result is obtained by using potassium dichromate, but even then the result is not satisfactory. B. Redlich treated lead hydroxide with a soln. of sodium chromate or dichromate. The tint of the product is influenced by the presence of acetic acid, sodium sulphate, etc. F. Auerbech and H. Pick obtained lead chromate by treating basic lead chromate with a dil. aq. soln. of sodium hydrocarbonate and chromate; and M. Gröger, by the action of water on potassium lead chromate. D. G. Fitzgerald and R. C. Molloy roasted chromic oxide or chromite with lead oxide; and J. Milbauer said that there is a 100 per cent. conversion to chromate when a mixture of chromic oxide and lead oxide or carbonate is heated to 480° in oxygen at 12 atm. press. G. Chancel obtained lead chromate by warming a soln. of chromic oxide in alkali-lye with lead dioxide, and treating the filtrate with acetic acid. H. Vohl heated lead nitrate and chromic oxide in a crucible; and K. Toabe treated lead with a soln. of chromic and nitric acids at 60° to 140°. A. C. Becquerel obtained crystals of the salt by placing a Pb–Pt-couple in a soln. of chromic chloride in a sealed tube.

C. Lückow prepared lead chromate by an electrolytic process. The electrodes are formed of soft lead and the electrolyte is composed of a 0·3 to 3·0 per cent. soln. of sodium chlorate (perchlorate, nitrate, or acetate) 80 parts and sodium chromate 20 parts. The current density was 0·5 amp. per sq. dm. The colour of the deposit varies with the nature of the soln., being yellow in an acidic soln., and inclining to red in an alkaline soln.; electrodes about 10 to 20 mm. apart, and 1·5 to 1·6 volts are needed for weakly acid soln.; about 1·7 volts for neutral soln., and 2 volts for weakly alkaline soln. M. le Blanc and E. Bindschedler found that in the electrolysis of soln. of sodium chlorate and chromate, containing 1·5 to 12 per cent. of salt—of which 70 to 90 per cent. is chlorate—by means of a lead anode, lead chromate is formed near the anode, separating from it by its own weight, whereas in soln. containing a large proportion of chromate an adherent layer of chromate and lead dioxide forms on the anode. The yield of lead chromate is theoretical in the first case, practically zero in the latter. Sodium nitrate, acetate, or butyrate give practically the same result as chlorate. With the mixed electrolyte, the current is mainly transported by ClO'_3-ions, the chromate ions are therefore soon removed almost completely from the electrolyte in contact with the anode, and the precipitation of lead chromate takes place at some small distance from it. With a more conc. chromate soln., this is not the case. K. Elbs and R. Nübling found that in the electrolysis of very dil. soln. of chromic acid with lead electrodes, lead chromate alone is obtained; with more conc. soln.—up to 40 or 50 per cent.—there is evidence of the formation at the anode of **plumbic chromate,** $Pb(CrO_4)_2$, or of a mixture of lead chromate and dioxide; and with very conc. soln.—130 grms. of CrO_3 per 100 c.c.—a soln. is obtained which evolves oxygen when kept and deposits lead dichromate. The quantity of oxygen evolved is in agreement with $Pb(Cr_2O_7)_2 = PbCr_2O_7 + 2CrO_3 + O$. According to G. Just, the potential difference between a lead anode and a soln. containing bivalent lead ions depends very much on the anodic current density (probably owing to local increase of the conc. of the lead ions) so that at high current densities it may rise to the normal value for lead dioxide. When this is the case, lead dioxide is, of course, formed on the anode. B. Huick electrolyzed a 1·5 per cent. soln. of a mixture of sodium chlorate (95 parts) and sodium dichromate (5 parts) for lead chromate.

As pointed out by E. E. Free, by using very dil. soln. of lead nitrate and potassium chromate—say M- to $\frac{1}{256}M$-soln.—yellow **colloidal solutions** are obtained which are stable for some days; and, if glue be present, the soln. are stable for many months. J. Milbauer and K. Kohn also found that in the presence of acetic acid, or when boiled, the colloidal lead chromate is flocculated. F. W. O. de Coninck observed that when crystalline lead chromate is boiled for one-half to one hour with a very conc. soln. of pure potassium nitrate and immediately filtered, the filtrate exhibits a well-marked red fluorescence and contains lead chromate. If, however, the filtrate after some moments is refiltered, the filter retains the lead chromate, and the second filtrate is colourless. Sodium nitrate behaves similarly, but much more slowly. It is thus inferred that the lead chromate is rendered colloidal by the nitrate soln. but that the colloidal form re-polymerizes very rapidly. W. Lenze obtained colloidal soln. by mixing 25 grms. of a 10 per cent. soln. of sodium protalbinate (or lysalbinate) with 15 grms. of a 20 per cent. soln. of lead acetate, and treating a soln. of the precipitate in soda-lye with a conc. soln. of potassium chromate, and adding enough acetic acid to prevent precipitation. The soln. was dialyzed. It is greenish-yellow in reflected light, and brown, in transmitted light. J. N. Mukherjee and H. L. Ray studied the adsorption of salts by precipitated lead chromate.

A. Drevermann obtained crystalline lead chromate by the very gradual diffusion of very dil. soln. of potassium chromate and lead nitrate into water. The solids were placed in separate cylinders, placed in a wide dish, and the dish filled with water above the tops of the cylinders. If air is present, some basic salt may be precipitated. L. Bourgeois said that besides the crystalline chromate some amorphous basic chromate may be precipitated. H. Vohl also obtained the crystals by allowing soln. of a lead salt and a chromate to diffuse into each other through a porous diaphragm. E. Hatschek studied the **rhythmic precipitation** of lead chromate. A small quantity of 0·5 per cent. soln. of potassium dichromate is introduced into a tube containing a one per cent. agar-agar jelly containing 0·1 per cent. of lead acetate. The diffusion of the soln. into the jelly is accompanied by the formation of a stratified system. If a second small quantity of dichromate is added when the first has completely disappeared, it is found that the diffusion of the newly-added dichromate gives rise to a second system of strata, in which the successive bands are much broader than those in the first system. The fact that two different systems can be obtained in the same jelly is considered to be irreconcilable with the supersaturation theory which has been advanced to account for the formation of these stratified systems. The subject was investigated by R. E. Liesegang, E. R. Riegel and L. Widgoff, S. C. Bradford, E. Hatschek, P. B. Ganguly, V. Moravek, A. C. Chatterji and N. R. Dhar, D. N. Ghosh, and K. Ando.

The mineral crocoite occurs crystalline, and in imperfectly columnar or granular masses coloured various shades of bright hyacinth-red, or orange-red. The crystals are feebly pleochroic. The **colour** of the artificial crystals is also orange-red. When the crystals are finely powdered, the colour is yellow, like that of the precipitated cryptocrystalline or amorphous powder. Normal lead chromate, prepared by precipitation, is a clear yellow and its use as a pigment explains why so many investigations have been made on processes of manufacture with the object of increasing the purity and clarity of the colour of *chrome-yellow*—light, medium, and dark. Some of these terms are also applied to other chromate yellows, *jaune de chrome*, *giallo di cromo*, *amarillo de cromo*, or *Chromgelb*—light, medium, and dark. It also has the trade-names *Paris yellow*, *King's yellow*, a term also applied to orpiment. The paler tints—*lemon-chrome*, and *citron-chrome*—are produced by mixing lead chromate with lead sulphate. By increasing the basicity of the chromate the colour is deepened, and reddened ; so that an unbroken series of colours can be obtained varying from the pure yellow of the normal chromate to the deep orange-red of the basic salt—*orange-chrome*, *chrome-red*, which also has the trade-names *chrome-cinnabar*, *chrome-garnet*, *chrome-ruby*, *Austrian red*, *Vienna red*, *Derby red*, *American Vermilion*, *rouge de Perse*, etc. The variations of colour among different samples of the same compound may be greater than with different compounds. The variation in colour may be due to differences in the basicity, hydration, average grain-size, etc. ; and it is conditioned by the temp., and conc. of the soln., by the time occupied in the precipitation ; and by the nature of the soln. which in turn affects the salts adsorbed by the precipitated chromate. The subject was discussed by J. Milbauer and K. Kohn, L. Bock, C. O. Weber, K. Jablczynsky, J. W. Bain, F. Rose, G. Zerr, G. Zerr and G. Rübencamp, E. Guignet, J. G. Gentele, and J. Bersch. E. E. Free said that for clear yellow colours, the formation of basic salts must be avoided. The presence of a slight trace of alkali, or a higher temp. than usual, may cause a darkening of the yellow colour. This darkening is produced by a number of unrecognized causes, but P. Grouvelle, and M. Dullo considered that in many cases the alteration of the colour is a visible sign that the normal chromate has undergone a partial change to the basic condition, produced by the presence of alkali. This is confirmed by the fact—observed by S. M. Godon de St. Menin, L. N. Vauquelin, C. O. Weber, and H. W. Hofmann—that the presence of small amounts of free acid in the soln. lessens the tendency for the colour to turn. C. O. Weber also noticed that an excess of chromate in the precipitating soln. favours the tendency of the colour to change, while an excess of lead salt acts in the converse way; but M. Dullo does not agree with this statement. E. E. Free suggested that in some cases the darkening of the colour may be due to the growth of the fine granules into coarser grains. The darkening of the colour may render the chrome-yellow quite useless for a pigment.

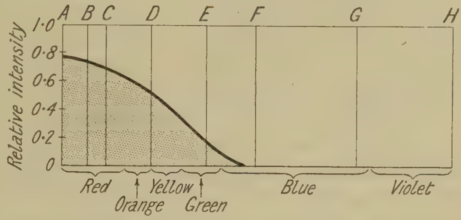

Fig. 58.—The Spectrum of Light Reflected from Lead Chromate.

E. E. Free showed that the difference in the colour of the yellow colour of the powder and the orange colour of the crystals is due to differences in the grain-size. The largest crystals are obtained with hot dil. soln. The size of the precipitated crystals increases continuously with decrease in conc. The colours of the precipitates obtained from the most conc. and the most dil. soln. are lighter than is the case with precipitates from soln. of intermediate conc. The curve shows a maximum depth of colour at moderate conc. So that size of grain alone does not suffer to explain the results. It is assumed that the basicity as well as grain-size were concerned in the effects obtained. A. Habich, T. Gobel, and J. Bersch showed that the larger crystals of the basic chromates correspond with the deeper and redder shades of colour; and W. E. Fuss stated that chrome-red, when ground, acquires a yellow tinge. B. Redlich said that chromates prepared by the action of chromate soln. on lead hydroxide are redder when the hydroxide is crystalline. E. L. Nichols and B. W. Snow showed that the reflection spectrum of pigments is produced by light reflected from the surface, and by light reflected from the interior faces. That reflected from the surface is white; and that reflected from the interior determines the colour of the pigment. The internally reflected light is that light which has entered at least one of the crystals and been reflected from the posterior surface of that crystal or from the surface of some other crystal situated more deeply within the mass. E. E. Free continued: with a more finely powdered pigment, there will be obviously more surface per unit of mass, and the first of these interior faces will be on the average nearer the external surface of the layer, that is, the layer of coloured material through which the internally reflected ray must pass, is less in the finely powdered material. It must therefore happen that the selective absorption which takes place in this ray will be relatively weaker, or in common phrase the "colour" imparted to the ray will be less marked. Crystalline lead chromate, however, changes from a reddish-orange to a clear yellow when powdered; so that there appears to be not only a weakening of the colour, but an actual change from red or orange into yellow. E. L. Nichols found that when light is reflected from a thin plate of lead chromate, the blue and violet, most of the green, and a considerable fraction of the yellow are absorbed, but the red is allowed to pass in greater degree and in increasing proportion with increasing wave-length. This is shown by Fig. 58, where the abscissæ represent wave-lengths, and the ordinates of the intensities of the reflected light in terms of uniform white light. The green component of the light which reaches the eye is masked by the larger proportion of red, and the apparent colour is a shade of yellow or orange tinged with red. By increasing the thickness of the plate, the area representing the absorbed light extends towards the left, thus concentrating the red and reducing the yellow. Conversely when the thickness of the plate is decreased, the green progressively weakens the red and makes the yellow more prominent in the transmitted light. As the transmitted light extends into the blue, a further decrease in the thickness of the plate, the blue tends to neutralize the yellow, as the green neutralizes the red, and the yellow becomes paler and paler, until in the limiting case the colour appears white. L. Godard studied the effect of radiant heat rays by chrome-yellow. Lead chromate belongs to the class of substances which W. Ackroyd called metachromatic because they change their colour on heating. The colour was shown by R. F. Marchand, L. Bourgeois, and E. J. Houston and E. Thomson to change from yellow to orange to red, and in this respect, it behaves like the majority of other substances observed by C. F. Schönbein, and E. J. Houston and E. Thomson, in that the maximum intensity, with rise of temp., moves towards the red. The basic chromates also become a deeper red when heated. Conversely, as the yellow chromate is cooled to —30° to —40°, it becomes yellowish-green; and M. Bamberger and R. Grengg said that both the natural and artificial crystals are decolorized at —190°.

The **crystals** of crocoite are monoclinic prisms; and, according to H. Dauber, the axial ratios are $a:b:c=0{\cdot}9603:1:0{\cdot}9159$, and $\beta=102°\ 27'$; E. F. Chirva gave $a:b:c=0{\cdot}960293:1:0{\cdot}91305$, and $\beta=77°\ 32'\ 55''$. The crystals are usually prismatic, but the habit varies so that the crystals sometimes resemble acute rhombohedra. The faces are usually smooth and brilliant; the (110) face may be vertically striated. The (110)-**cleavage** is distinct; but the (001)- and (100)-cleavages are not so well defined. The crystals were also examined by N. von Kokscharoff, and F. Hessenberg. A. de Schulten, A. Drevermann, and L. Bourgeois also showed that the artificial crystals are monoclinic prisms. B. Gossner and F. Mussgnug showed that the **X-radiograms** correspond with $a=6{\cdot}82$ A., $b=7{\cdot}48$ A., $c=7{\cdot}16$ A., and $\beta=102°\ 33'$; or $a:b:c=0{\cdot}912:1:0{\cdot}957$. The vol. of unit cell is $356{\cdot}5\times10^{-24}$ c.c. G. Tammann and Q. A. Mansuri found that the recrystallization of the powder with granules less than 0·3 mm. begins between 237° and 248°. The **optical character** is positive; and the **optic axial angle** $2V=54°$. In accord with the dimorphism of lead sulphate, discussed by W. Grahmann, P. Groth and K. Haushofer said that lead chromate is probably dimorphous furnishing monoclinic and rhombic crystals. C. Lüdeking obtained artificially what he regarded as rhombic crystals—*vide supra*. According to F. M. Jäger and H. C. Germs, lead chromate is trimorphic. The monoclinic or α-form is stable below 707°; the β-form is stable between 707° and 783°; and the γ-form between 783° and the m.p. 920°—Fig. 62. The transition $\alpha\text{-PbCrO}_4\rightleftharpoons\beta\text{-PbCrO}_4$, at 707°, is attended by a small thermal change, while the transition $\beta\text{-PbCrO}_4\rightleftharpoons\gamma\text{-PbCrO}_4$, at 783°, involves a greater thermal change. Some varieties of crocoite showed only one transition temp. at 792°.

C. H. D. Bödeker gave 5·951–6·004 for the **specific gravity** of lead chromate; L. Playfair and J. P. Joule, 5·653; and P. Niggli, 6·123. H. G. F. Schröder gave 5·965 for the sp. gr. of crocoite; and for the artificial crystals, N. S. Manross gave 6·118; A. de Schulten, 6·123 at 15°; L. Bourgeois, 6·29; J. Milbauer and K. Kohn gave 5·44 for that of the amorphous precipitate. B. Gossner and F. Mussgnug calculated 6·00 for the sp. gr. The **hardness** of crocoite is 2·5 to 3·0. P. W. Bridgman found the linear **compressibility** at 30°, in the direction C of the monoclinic crystals, to be $\delta l/l_0=0{\cdot}0_64978p-0{\cdot}0_{11}378p^2$, and at 75°, $\delta l/l_0=0{\cdot}0_65102p-0{\cdot}0_{11}422p^2$ for press. p ranging up to 12,000 kgrms. per sq. cm. H. Kopp gave 0·0900 for the **specific heat** between 19° and 50°; and 29·0 for the mol. ht. T. M. Lowry and L. P. McHatton observed that the fineness of the powder produced by the decrepitation of crocoite depends on the proportion of included water which the mineral contains. R. F. Marchand said that lead chromate fuses at a red-heat and, on cooling, solidifies to a dark brown mass which forms a brownish-yellow powder ; but if the molten chromate be poured into cold water, it forms a red mass which yields a red powder. F. M. Jäger and H. C. Germs found that the **melting point** of lead chromate is 844°—and fusion is attended by a little decomposition ; while crocoite melts at 835° to 839°. R. F. Marchand said that when heated above its m.p., it gives off about 4 per cent. of oxygen forming lead dichromate and chromic oxide. The amount of oxygen evolved is only a fractional part of that which would be evolved if the decomposition were complete. R. F. Marchand represented the reaction : $4PbCrO_4=2Pb_2O(CrO_4)+Cr_2O_3+3O$; C. Schubert, and W. Hempel and C. Schubert found that the evolution of gas begins at about 600°, and he observed rather more oxygen is given off up to 1150° than is required by this equation. If re-heated in oxygen gas, the chromate is not reformed ; but if a mixture of chromic oxide and lead oxide be heated in oxygen, 14·9 parts of oxygen are taken up for 100 parts of chromic oxide. W. Hempel and C. Schubert found that dissociation begins at about 600°, and is completed at 1150°. R. Lorenz and W. Herz studied some relations between the b.p. and the critical temp. H. C. Sorby gave 2·730 for the **index of refraction** of crocoite ; C. Bärwald gave 2·203 and 2·667 for red-light, and 2·437 and 2·933 for green-light ; while A. des Cloizeaux gave 2·42 for yellow-light. A. de Gramont examined the **spark spectrum** of crocoite. G. H. Hurst found that chrome-yellow reflects a large proportion of the yellow and green rays, with a small quantity of orange and blue rays, Fig. 59. G. I. Pokrowsky studied the polarization of light by finely divided lead chromate suspended in water. W. W. Coblentz gave for the diffuse reflecting power :

λ . . .	0·54μ	0·60μ	4·4μ	8·8μ	24·0μ
Emission .	61·2	70·2	41·2	4·74	7·4

T. W. Case said that the **electrical resistance** of crocoite exceeds one megohm, and is not affected by light. The sp. **electrical conductivity** of a sat. soln. at 18° was found by F. Kohlrausch to be of the order $0·1\times10^{-6}$ mhos. According to J. Rosenthal, the electrical conductivity of the compressed powder increases with temp., being 0·110 mho at 208°, and 0·385 mho at 331°. The precipitated powder is a better conductor than that obtained by grinding the fused chromate. R. Labes studied the electrical charges on the surface of lead chromate in soln. of electrolytes.

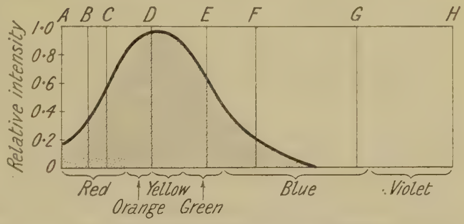

Fig. 59.—Reflection Spectrum of Chrome-yellow.

E. Rutherford and F. Soddy observed that red-hot lead chromate has no action on **radium or thorium emanation.** R. F. Marchand observed that when lead chromate is heated in **hydrogen,** water is formed and the mass becomes incandescent before the temp. of the vessel had attained a red-heat. The reaction is symbolized $2PbCrO_4+5H_2=5H_2O+Cr_2O_3+2Pb$. H. Mennicke found that hydrogen *in statu nascendi*—from hydrochloric acid and zinc in the presence of platinum—reduces lead chromate quickly and completely. J. Milbauer and K. Kohn said that when the yellow chromate is warmed with **water** it becomes red, but on cooling the yellow colour is restored ; and A. J. Cox found that at 25°, the chromate is hydrolyzed so that the water contains about 0·02 millimol of chromic acid per litre. J. F. G. Hicks and W. A. Craig studied the progressive hydrolysis of lead chromate by water at 100° at ordinary press., and in sealed tubes ; and found that the reaction is complete in about 3 hrs. A basic lead chromate is formed. The older chemists thought that lead chromate is insoluble in water, but A. Drevermann found that 1000 parts of water dissolve 0·02 part of salt; and P. Harting said that lead nitrate is precipitated as chromate when one part is present in 70,000 parts of water. G. von Hevesy and F. Paneth gave for the solubility $1{\cdot}2\times10^{-5}$ grm. per litre at 25°; G. von Hevesy and E. Rona gave 2×10^{-7} mol per litre at 20°; F. Kohlrausch and F. Rose, 0·0002 grm. per litre at 18°; F. Kohlrausch, 0·0001 grm. per litre at 18°; K. Beck and P. Stegmüller, 3×10^{-7} mol per litre at 25°. F. Auerbach and H. Pick gave for the solubility product, $[Pb''][CrO_4'']=2\times10^{-14}$ at 18°; and $[Pb'']^2[CrO_4''][OH']^2=6\times10^{-35}$. P. Schützenberger observed that when heated in a porous crucible over a gas-flame, lead chromate adsorbs moisture which is expelled only at a red heat. K. B. Lehmann observed that conductivity water dissolves more than distilled water. According to L. N. Vauquelin, lead chromate dissolves completely in a soln. of **potassium hydroxide**; and F. Wöhler and J. von Liebig added that the soln., sat. while hot, deposits after a few days yellowish-red laminæ of a basic salt. A. Drevermann also said that a soln. of potassium hydroxide makes the crystals opaque, and darker, and they are then slowly dissolved. M. Lachaud and C. Lepierre found that a litre of $2N$-KOH dissolves 11·9 grms. of lead chromate at 16°; 16·2 grms. at 60°; 26·1 grms. at 80°; and 38·5 grms. at 102°, forming $K_2Pb(CrO_4)_2$. Conc. potash-lye—say 45 per cent. KOH, sp. gr. 1·47—forms oxychromate, or lead monoxide; but $2N$-KOH forms only the oxychromate. Molten potassium hydroxide forms crystals of the oxychromate—*vide infra*, basic salts. R. Eberhard observed that the salt is soluble in an alcoholic soln. of potassium hydroxide. According to F. Brandenburg, when lead chromate is boiled with a soln. of **potassium carbonate**, a basic oxychromate is formed, and then lead carbonate; the liquid takes up much chromic and lead oxides, and when treated with sulphuric acid, lead chromate is precipitated. The observations of H. Golblum and G. Stoffella on the equilibrium $PbCrO_4+Na_2CO_3\rightleftharpoons PbCO_3+Na_2CrO_4$ have been summarized in Fig. 60. K. B. Lehmann found that a dil. soln. of sodium carbonate readily dissolves lead chromate and a state of equilibrium is inaugurated with the oxychromate: $2PbCrO_4+2Na_2CO_3+H_2O\rightleftharpoons PbO.PbCrO_4+2NaHCO_3+Na_2CrO_4$. With increasing dilution and rise in temp. the equilibrium is displaced towards the right-hand side of the above equation. When the equilibrium is approached from the side of the basic lead chromate, exactly the same results are not obtained as from the side of the normal lead chromate. The reversible reaction expressed by the equation: $PbCrO_4+Na_2CO_3\rightleftharpoons PbCrO_3+Na_2CrO_4$, only takes place in the presence of considerable quantities of hydrocarbonate in soln., otherwise basic lead chromate is formed. For soln. with the total sodium conc. from $0{\cdot}05N$- to $0{\cdot}1N$-Na_2CO_3, at 18°, the equilibrium constant, for the reaction $2PbCrO_4+2CO_3''+H_2O\rightleftharpoons PbO.PbCrO_4+CrO_4+2HCO_3'$ is $[CrO_4''][HCO_3']^2/[CO_3'']^2=0{\cdot}057$—$CQ'$, Fig. 60; for $2PbCO_3+CrO_4''+H_2O\rightleftharpoons 2HCO_3'+PbO.PbCrO_4$, it is $[HCO_3']^2/[CrO_4'']=1{\cdot}95$—$Q'B$, Fig. 60; and for $PbCrO_4+CO_3''\rightleftharpoons CrO_4''+PbCO_3$, it is $[CrO_4'']/[CO_3'']=0{\cdot}2$—$AQ'$, Fig. 60; and if carbonic acid be present, $[H_2CO_3][CrO_4'']/[HCO_3]^2=4\times10^{-5}$. Lead chromate enters into reversible reaction with a soln. of sodium hydrocarbonate according to the equation: $PbCrO_4+2NaHCO_3\rightarrow PbCO_3+Na_2CrO_4+CO_2+H_2O$; equilibrium is attained at a much lower press. of carbon dioxide than is the case with lead sulphate. The equilibrium conditions for the ternary system: Na_2CO_3–$NaHCO_3$–

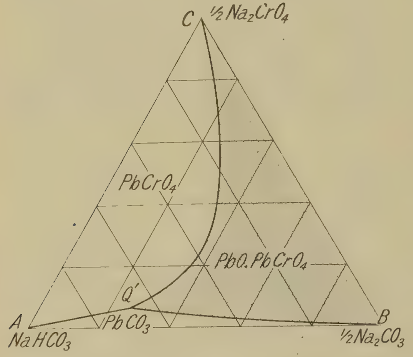

Fig. 60.—Equilibrium between Lead Chromate and $0{\cdot}1N$-Sodium Carbonate Solutions at 18°.

Na_2CrO_4 in the presence of lead chromate, oxychromate and carbonate, are shown in Fig. 60. The region where lead carbonate is stable is very small, and the transformation $PbCrO_4+Na_2CO_3\rightleftharpoons PbCO_3+Na_2CrO_4$ occurs only in the presence of hydrocarbonate. The regions of stability of the two lead chromates are very wide.

H. Moissan observed that **hydrogen chloride** decomposes lead chromate forming red fumes of chromyl chloride ; and H. Schwarz, that hot **hydrochloric acid** dissolves the chromate with the formation of chlorine, lead chloride, and chromic chloride. M. Gröger said that hot, dil. hydrochloric acid decomposes the chromate completely forming lead chloride which, if not filtered off, and water be added, re-forms lead chromate. K. Beck and P. Stegmüller found the solubility, S millimols per litre, to be :

	HCl	0·1*N*-	0·2*N*-	0·3*N*-	0·4*N*-	0·5*N*-	0·6*N*-
S	18°	0·186	0·393	0·654	1·07	1·56	2·25
	25°	0·239	0·485	0·839	1·32	4·06	2·95
	37°	0·337	0·744	1·31	2·10	3·28	4·69

so that, as indicated by K. B. Lehmann, the solvent action is greater, the more conc. the acid. A conc. soln. of sodium chloride dissolves traces of the chromate ; and M. Lachaud and C. Lepierre stated that molten sodium chloride converts the chromate into basic chromates. J. F. G. Hicks, and J. F. G. Hicks and W. A. Craig found that reactions in fused salts can be brought about to yield products analogous to those obtained with the same initial substances in aq. soln., the chief difference being the slowness of the reactions in the fused medium at 870°. The reaction with fused **sodium chloride** represents a true state of equilibrium. A basic chromate is the main product of the reaction. J. Milbauer and K. Kohn found that lead chromate reacts quantitatively with **potassium iodide :** $CrO_4''+8H^{\cdot}+3I'=Cr^{\cdots}+4H_2O+3I$. M. le Blanc and E. Bindschedler found lead chromate to be insoluble in contact with a 1·5 per cent. soln. of **sodium chlorate** for 4 hrs. at room temp. H. H. Willard and J. Kassner found that the solubility of lead chromate in **perchloric acid,** S grm. per 100 c.c. at 25°, is :

M-$HClO_4$	0·1	0·5	1·0	2·0	3·0	4·0	5·0
S	0·0041	0·0120	0·0140	0·0199	0·0211	0·0213	0·0191

The solubility is reduced if lead perchlorate or sodium dichromate be present.

J. B. Senderens said that the chromate is not altered when boiled for a week with water and **sulphur.** The presence of free sulphur, or **sulphides,** gradually darkens chrome-yellow owing to the formation of lead sulphide. E. F. Anthon heated in a glass tube a mixture of lead chromate with one-eighth of its weight of sulphur, and found that the product takes fire with incandescence on exposure to air, forming sulphur dioxide, and chromic and lead oxides. H. Moissan and P. Lebeau said that **sulphur hexafluoride** is not decomposed by molten lead chromate. Hot sulphuric acid decomposes lead chromate, forming lead sulphate, and H. Schwarz found that for complete decomposition an excess of 4 to 5 mols of sulphuric acid is necessary ; M. Gröger found that the decomposition with boiling dil. sulphuric acid is incomplete ; the cold conc. acid acts slowly while the hot acid acts quickly, forming chromic acid. J. Milbauer and K. Kohn's observations on the reaction with **potassium sulphate** soln. are summarized in Fig. 55. G. Chancel said that lead chromate is insoluble in a soln. of **sodium thiosulphate.**

E. C. Franklin and C. A. Kraus found that lead chromate is insoluble in liquid **ammonia ;** and W. E. Garrigues that it is insoluble in aq. ammonia. C. L. Parsons found that lead chromate favours the oxidation of ammonia by air. R. H. Brett said that the salt is insoluble in a soln. of ammonium chloride. A. Drevermann, J. von Liebig, and A. Baumann observed that lead chromate is insoluble in nitric acid. E. Duvillier stated that boiling conc. **nitric acid** dissolves 98·79 per cent. CrO_3 and only 1·21 per cent. PbO, while the remaining lead separates as lead nitrate. When water is added to the mixture, lead chromate is reformed. K. Beck and P. Stegmüller gave for the solubility S millimols Pb per litre, at 18°,

HNO_3	0·1N-	0·2N-	0·3N-	0·4N-	0·5N-	0·6N-
S	0·129	0·227	0·312	0·401	0·488	0·598

H. H. Willard and J. L. Kassner found the solubility of lead chromate, S grm. per 100 c.c. at 25°, in nitric acid, to be :

M-HNO_3	0·1	0·5	1·0	2·0	3·0	4·0	5·0
S	0·0063	0·0177	0·0385	0·0889	0·1701	0·2812	0·4367

The solubility is reduced if lead nitrate, or sodium dichromate be present. C. Marie said that 0·5 grm. of lead chromate dissolves in a mixture of nitric acid with 2 grms. of **ammonium nitrate.** F. Wöhler and J. von Liebig found that molten **potassium nitrate** converts lead chromate into the oxychromate ; and M. Lachaud and C. Lepierre observed the formation of the complex salts $K_2Pb(CrO_4)_2$ and $2PbO.K_2Pb(CrO_4)_2$. Similarly also with sodium and lithium nitrates. J. F. G. Hicks, and J. F. G. Hicks and W. A. Craig studied the reaction with an equimolar mixture of fused sodium and potassium nitrates at various temp. up to 230°. The reaction at different temp. represents states of equilibrium analogous to hydrolysis. The product of the reaction is a basic chromate. F. W. O. de Coninck studied the peptizing action of a boiling soln. of potassium nitrate on lead chromate—*vide supra.* K. Jellinek and H. Ens found that 3 drops of a one per cent. soln. of **silver nitrate** are coloured reddish-brown owing to the formation of silver chromate.

H. Moser observed that when heated with **carbon,** lead chromate is reduced to lead and chromic oxide. E. Berger and L. Delmas found that the combustion of carbon in air is facilitated by the presence of lead chromate. M. Tarugi found that at 400°, **calcium carbide** reduces the chromate to a calcium lead alloy and chromium. A. Kutzelnigg observed that lead chromate exerted an oxidizing action on a soln. of **potassium ferrocyanide ;** and J. R. Campbell and T. Gray, that the salt exerts an oxidizing action on **methane** and **ethylene.** K. B. Lehmann found that conc. **acetic acid** dissolves very little lead chromate ; and A. Baumann, that acetic acid dissolves no chromate. Lead chromate is almost insoluble in a soln. of **ammonium acetate ;** and, according to I. M. Kolthoff, in a soln. of **sodium acetate.** H. C. Bolton found that a boiling conc. soln. of **citric acid** decomposes crocoite. J. Spiller said that lead chromate is not precipitated in the presence of **alkali citrates ;** and A. Naumann, that it is insoluble in acetone. J. B. Charcot and P. Yvon said that **saliva** dissolves perceptible amounts of lead chromate. L. Vignon stated that fabrics are usually dyed with lead chromate by passing the material through the aq. soln. of a soluble lead salt and then through a soln. of potassium or sodium chromate. Dyeing also occurs if the material is agitated in a suspension of precipitated lead chromate in water ; equally good results are obtained with silk, wool, or cotton. The lead chromate does not combine chemically with the material dyed. Dyeing also takes place if the lead chromate is suspended in alcohol or benzene, but the resulting colours are not so deep as those obtained when water is the medium of suspension. The reaction was studied by M. A. Iljinsky and V. V. Kozloff.

P. Jannasch observed that natural **silicates** are decomposed when heated strongly with lead chromate. L. Kahlenberg and W. J. Trautmann found that when mixed with silicon and heated by a bunsen burner a sudden reaction occurs with the evolution of heat and light. There is a strong reaction at a " cherry " red-heat and when heated in the electric arc. E. Lay found that **silicon hydrotrinitride** reduces lead chromate at a high temp. M. Lachaud and C. Lepierre found that a soln. of **chromic acid** causes amorphous lead chromate to crystallize, or, according to K. Preis and B. Rayman, to be transformed into lead dichromate ; but, according to W. Autenrieth, a hot, conc. soln. of chromic acid does not dissolve the chromate.

J. Coneybeare said that lead chromate dissolves sparingly in water containing **potassium chromate.** F. Paneth and co-workers, G. M. Schwab and E. Pietsch, and A. Eisner studied the adsorption of radioactive substances by crystals of lead chromate. J. N. Mukherjee and H. L. Ray found that a precipitate of lead chromate in contact with various salts becomes negatively charged in contact with water, this being due, probably, to the adsorption of chromate ions or, alternatively, to the adsorption of hydroxyl ions from the water. The velocity of electrical-osmosis shows that when the lead chromate is in contact with soln. of potassium chromate, iodate, nitrate, iodide, sulphate, and chloride, lead nitrate, barium chloride, and calcium chloride of conc. varying between 0·000067*N* and 0·004*N*, the order of adsorbability of the cations is $Pb^{\cdot\cdot} > Ba^{\cdot\cdot} > Ca^{\cdot\cdot} > K^{\cdot}$, whilst with a constant cation, $K^{\cdot}$, the order of adsorption of the anions is that given above. The constituent ions of a precipitate are very strongly adsorbed by it, those of lead being so largely adsorbed as to reverse the charge at a conc. of 0·00005*N*. These observations cannot be explained on the type of adsorption assumed by F. Paneth; and the suggestion of K. Fajans and K. von Beckerath that there is a parallelism between the intensity of adsorption of the anion and the solubility of the salt of the adsorbed ion with opposite sign in the precipitate is not tenable, since the nitrate is more strongly adsorbed than the iodide or sulphate, whereas the order of increasing solubility of the lead salts is $CrO_4'' < IO_3' < I' < SO_4'' < Cl' < NO_3'$. F. M. Jäger and H. C. Germs studied the binary system: **lead sulphate**—and lead chromate, and obtained the diagram, Fig. 61, which is largely conjectural because of the decomposition at the higher temp. There is a gap in the solid soln. between 30 and 40 per cent. $PbCrO_4$. The mixed crystals have transition points at 934°, 874°, and 748°.

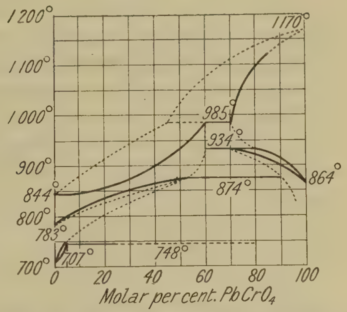

FIG. 61.—Freezing-point Curves of the Binary System: $PbSO_4$–$PbCrO_4$.

A number of **basic lead chromates** has been reported. C. Lückow, and J. J. W. Watson and T. Slater obtained basic salts by the electrolysis of a soln. of sodium chlorate and chromate with lead electrodes; S. Ganelin, by the action of potassium chromate and magnesia on lead sulphate; A. C. Becquerel, by the action of a zinc plate and water on lead chromate; E. Toelle and M. von Hofe, and J. Kronen, by the action of a paste of lead chromate on lead oxide; H. N. Holmes,

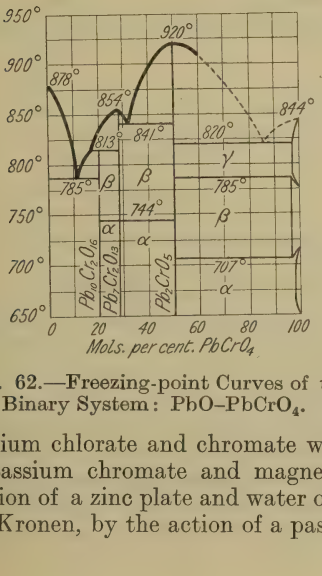

FIG. 62.—Freezing-point Curves of the Binary System: PbO–$PbCrO_4$.

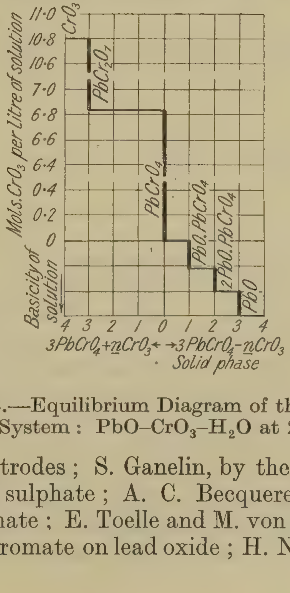

FIG. 63.—Equilibrium Diagram of the Ternary System: PbO–CrO_3–H_2O at 25°.

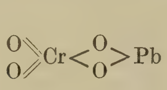
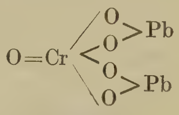
by the action of potassium chromate on soln. of lead salts; and A. Prinvault observed transient violet compounds of apparently high basicity. The equilibrium conditions of fused mixtures of lead oxide and chromate were studied by H. C. Germs, F. M. Jäger and H. C. Germs, J. F. G. Hicks. The f.p. curve of the binary system by F. M. Jäger and H. C. Germs is shown in Fig. 62. The compound Pb_5CrO_8, or $Pb_{10}Cr_2O_{16}$, has no real m.p. and is stable only below 815°. The eutectic between $PbCrO_4$ and Pb_2CrO_5 occurs at 820°, but this part of the diagram could not be accurately explored because of decomposition. The other basic salt was $Pb_7Cr_2O_{13}$. J. F. G. Hicks obtained Pb_2CrO_5, as well as Pb_4CrO_7; Pb_3CrO_6; and $Pb_3Cr_2O_9$ on his f.p. curve; but the results were obtained by a cruder method. The compounds obtained by the f.p. process, are not necessarily the same as those obtained by wet processes. The results of A. J. Cox's examination of the ternary system: $PbO–CrO_3–H_2O$ at 25°, are summarized in Fig. 63. Here, the basic salts Pb_3CrO_6 and $PbCrO_5$ were obtained—*vide supra,* mercury chromates.

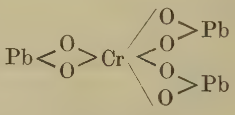
F. M. Jäger and H. C. Germs observed that **lead tetroxychromate,** $5PbO.CrO_3$; $4PbO.PbCrO_4$; Pb_5CrO_8; or $Pb_{10}Cr_2O_{16}$, is formed from mixtures of lead chromate with 82·5 to 89 molar per cent. of lead oxide, Fig. 62. The compound is stable below 815°. It decomposes with the evolution of oxygen above its m.p.; and at a temp. exceeding 615°, it decomposes into a liquid and solid β-$Pb_7Cr_2O_{13}$. J. F. G. Hicks obtained **lead trioxychromate,** $4PbO.CrO_3$; $3PbO.PbCrO_4$; or Pb_4CrO_7, from a molten mixture of lead oxide and chromate, but F. M. Jäger and H. C. Germs did not find it—Fig. 62. D. Strömholm added the calculated amount of $0·1N$-K_2CrO_4 to lead hydroxide, and as soon as equilibrium was established; there remained an ochre-yellow mass of small needles of the *monohydrate* of lead trioxychromates, $Pb_4CrO_7.H_2O$. F. M. Jäger and H. C. Germs observed the formation of **lead pentoxybischromate,** $7PbO.2CrO_3$; $5PbO.2PbCrO_4$; or $Pb_7Cr_2O_{13}$, by melting lead chromate with 68 to 82·5 molar per cent. of lead oxide, Fig. 62. It melts at 854° with feeble dissociation. At 774°, there is a reversible transformation with a small thermal change. It forms with lead oxychromate a eutectic at 841° and 68 molar per cent. PbO. They consider that the mineral *melanochroite* from Beresowsk, Urals, is probably this compound—*vide infra.* At 830°, this melanochroite decomposes with the separation of lead. J. F. G. Hicks reported **lead dioxychromate,** $3PbO.CrO_3$; $2PbO.PbCrO_4$; or Pb_3CrO_6, to be formed from fused mixtures of lead oxide and chromate, but F. M. Jäger and H. C. Germs did not find it. On the other hand, A. J. Cox observed its formation under the conditions indicated in Fig. 63. This salt can be regarded as a derivative of the hypothetical *orthochromic acid,* H_6CrO_6; just as $PbO.PbCrO_4$ can be regarded as a derivative of *parachromic acid,* H_4CrO_5.



$PbCrO_4$



$PbO.PbCrO_4$



$2PbO.PbCrO_4$

J. F. G. Hicks, however, does not favour this hypothesis, since it does not explain the constitution of $3PbO.PbCrO_4$.

P. L. Dulong prepared **lead oxychromate,** $2PbO.CrO_3$; $PbO.PbCrO_4$; or Pb_2CrO_5, by boiling lead oxide or carbonate with an aq. soln. of potassium chromate. M. Rosenfeld, F. Auerbach and H. Pick, T. Göbel, and J. G. Gentele employed modifications of this process—*cf.* Figs. 62, and 63. L. N. Vauquelin, and M. Faraday exposed to the air a dil. soln. of lead nitrate and potassium chromate in dil. potashlye, and obtained small crystals which was thought were the normal chromate, but which were shown by F. Wöhler and J. von Liebig to be the oxychromate. C. Reichard obtained the oxychromate by the action of potassium chromate on a soln. of lead sulphate in an aq. soln. of ammonium tartrate; R. Weinland and F. Paul, by the action of potassium chromate on a hot soln. of potassium hydroxychlorate; and A. A. Hayes, by the slow action of carbon dioxide on a soln. of lead oxide and potassium chromate in potash-lye. As the soln. becomes sat. with carbon dioxide, orange-yellow needles of lead oxychromate are formed. F. M. Jäger and H. C. Germs observed that this compound is formed by the fusion of mixtures of lead chromate with 15 to 68 molar per cent. PbO—Fig. 62. J. F. G. Hicks obtained it in a similar manner; and R. F. Marchand, by heating the neutral chromate to redness for some time. A. A. Hayes, J. F. G. Hicks, W. E. Fuss, J. F. G. Hicks and W. A. Craig, F. Wöhler and J. von Liebig, M. Gröger, L. Bourgeois, and M. Lachaud and C. Lepierre obtained it by fusing lead chromate with an alkali nitrate, and leaching out the soluble salt with water. M. Lachaud and C. Lepierre, and J. F. G. Hicks and W. A. Craig, by fusing a mixture of lead oxide and chromate, and sodium chloride. Lead oxychromate is also a product of the hydrolysis of the normal chromate with water or, according to E. F. Anthon, P. Grouvelle, J. F. G. Hicks, C. O. Weber, A. Habich, M. Lachaud and C. Lepierre, with dil. alkali-lye; or, according to F. Auerbach and H. Pick, with $0\cdot1N\text{-}Na_2CO_3$. P. L. Dulong, and E. Guignet obtained the same basic salt by boiling lead chromate and carbonate with water; M. Rosenfeld, T. Göbel, P. Grouvelle, and J. Badams, by boiling lead chromate and oxide with water; and J. J. Berzelius, by boiling lead oxide with potassium chromate and water. R. Weinland and R. Stroh prepared the basic chromate **lead dihydroxychromate,** $[Pb(OH)_2]CrO_4$, by double decomposition with lead perchlorate and a soluble chromate. The equilibrium conditions were studied by A. J. Cox—Fig. 63. Analyses were reported by D. Strömholm, M. Gröger, J. F. G. Hicks, M. Lachaud and C. Lepierre, F. Auerbach and H. Pick, J. Badams, etc. The colour of this basic chromate varies from a deep fiery red, cochineal-red, scarlet-red, orange-red, vermilion, etc. Orange-chrome —*vide supra*—is mainly this compound. It may be formed as an amorphous, or eruptic crystalline powder; and the crystals were described by M. Lachaud and C. Lepierre as prismatic needles, which, according to L. Bourgeois, are isomorphous with lanarkite. F. M. Jäger and H. C. Germs said that it furnishes no polymorphic transformation, and that it melts at 920°. The eutectic with lead chromate is at 820° with about 15 molar per cent. of lead oxide. M. Lachaud and C. Lepierre said that it is insoluble in water; and F. Auerbach and H. Pick gave 6×10^{-35} for the solubility product at 18°. M. Lachaud and C. Lepierre found that a litre of $2N$-KOH at 15° dissolves 10·1 grms.; at 60°, 13·5 grms.; at 80°, 21·9 grms.; and at 102°, 32·1 grms. Dil. acids transform it into lead chromate. Observations on the action of sodium hydrocarbonate soln., by F. Auerbach and H. Pick, are summarized in Fig. 56. J. Badams said that acetic acid extracts half the contained lead oxide.

R. Hermann reported the occurrence of a basic lead chromate in the limestone of Beresowsk, Urals, and he called it **melanochroite**—from μέλας, black; and χρόα, colour—but since the colour of the mineral is red, not black, E. F. Glocker changed the name to *phoenicochroite*—from φοινίκεος, deep-red; and χρόα, colour—and this term was adopted by J. F. L. Hausmann, and J. D. Dana. W. Haidinger's term *phönicite* is more portable, so to speak, but it is too much like phenacite for use. R. Hermann's analysis corresponds with **lead oxybischromate,** $3PbO.2CrO_3$, $PbO.2PbCrO_4$, or $Pb_3Cr_2O_9$. W. E. Dawson gave $4PbO.3CrO_3$ for a variety obtained from Pretoria, Transvaal. Analyses of the artificial chromate in agreement with this were reported by C. Lüdeking, R. Weinland and F. Paul, and M. Lachaud and C. Lepierre. A. Drevermann obtained it together with the normal chromate by the slow mixing by diffusion of soln. of potassium chromate and lead nitrate. R. Weinland and F. Paul obtained it by the action of sodium chromate soln. on a hot soln. of lead hydroxychlorate. A. C. Becquerel obtained it by electrolysis, through a connecting capillary tube, of soln. of potassium dichromate and plumbate; by the electrocapillary action of the same two soln. separated by a collodion or paper partition; by the long continued action of a soln. of potassium chromate on chalk previously boiled with a conc. soln. of lead nitrate; and by the action for several years of a Pt–Pb-couple on a conc. soln. of chromic chloride and china clay. N. S. Manross, and M. Lachaud and C. Lepierre obtained it by heating at a red-heat a mixture of lead chromate and molten sodium chloride; S. Meunier, by the action of a soln. of potassium dichromate on galena; and C. Lüdeking, by allowing a soln. of lead chromate in conc. potash-lye to stand for some months exposed to air. F. M. Jäger and H. C. Germs observed no sign of this compound in their study of the system $PbO–PbCrO_4$; nor was A. J. Cox more successful in his study of the system: $PbO–CrO_3–H_2O$. J. F. G. Hicks, however, said that he obtained it from fused mixtures of lead oxide and chromate in a molten equimolar mixture of potassium and sodium nitrates. According to R. Hermann, melanochroite is coloured hyacinth-red or cochineal-red, and it becomes lemon-yellow on exposure to air. It occurs in massive, and also in tabular crystals thought to be rhombic. The sp. gr. is 3·0 to 3·5, and the hardness 5·75. A. Drevermann described it as forming rhombic plates coloured like potassium ferricyanide; A. C. Becquerel, as orange-red, doubly refracting needles; and N. S. Manross, as deep red, hexagonal prisms. M. Lachaud and C. Lepierre said that the red, rhombic crystals have a sp. gr. 5·81; A. Drevermann found that the salt does not dissolve as readily as the normal chromate in a soln. of potassium hydroxide. Conc. nitric acid changes it into chrome-yellow.

M. Gröger reported **ammonium lead chromate,** $(NH_4)_2Pb(CrO_4)_2$, by dropping 50 c.c. of a cold, sat. soln. of ammonium chromate into 10 c.c. of a conc. soln. of lead acetate, and allowing the voluminous, yellow, amorphous precipitate to stand for some weeks in contact with the mother-liquor. M. Lachaud and C. Lepierre obtained microscopic, hexagonal plates of **lithium lead chromate,** $Li_2Pb(CrO_4)_2$, by heating freshly precipitated lead chromate with a very conc., neutral soln. of lithium chromate for 8 hrs. in a sealed tube at 140°; and by melting lead chromate with lithium nitrate when some lead oxychromate is formed at the same time. A basic salt could not be prepared. Normal **sodium lead chromate,** $Na_2Pb(CrO_4)_2$, was obtained in a similar way. The yellow prisms or plates are soluble in water. By heating lead chromate, lead oxychromate and sodium chromate in molten sodium nitrate, orange, microscopic prisms of **sodium lead dioxybischromate,** $2PbO.Na_2Pb(CrO_4)_2$, are produced. M. Barre obtained **potassium lead chromate,** $K_2Pb(CrO_4)_2$, from soln. of potassium chromate and lead chromate; L. Bourgeois, and M. Lachaud and C. Lepierre, obtained it by heating lead chromate, or a mixture of lead chromate and potassium chromate in molten potassium nitrate for 3 hrs.; and M. Gröger, by shaking 50 c.c. of an almost sat. soln. of potassium chromate with 10 c.c. of a conc. soln. of potassium acetate—with lead nitrate some hydroxynitrate is formed as well. The yellow, hexagonal plates melt in a crucible over the bunsen flame. The salt is insoluble in water and in alcohol; and with dil. acids, lead chromate is formed. According to M. Barre, the salt is decomposed by water, potassium chromate passing into soln., but with the following proportions of potassium chromate in 100 parts of water, the salt is insoluble at the temp. indicated:

	10°	27·5°	37·5°	50°	70°	100°
K_2CrO_4 . . .	8·950	8·077	7·629	7·150	6·145	4·940

C. Immerwahr said that the electrode potential of lead against lead chromate suspended in $2M$-K_2CrO_4 is 0·536 volt. M. Gröger said that the *monohydrate,* $K_2Pb(CrO_4)_2.H_2O$, is formed by the action of lead chromate on potassium acetate soln., or of potassium chromate on lead acetate soln. M. Lachaud and C. Lepierre obtained **potassium lead dioxychromate,** $2PbO.K_2Pb(CrO_4)_2$, in orange prisms by the method used for the sodium salt. M. Lachaud and C. Lepierre also prepared **barium, strontium, and calcium lead chromates** by the method used for the alkali salts. For **copper lead chromate,** *vide infra,* vauquelinite. A. Breithaupt described a mineral from Berezoff, Urals, as occurring in orange-yellow crystals—possibly **zinc lead chromate.** The mineral was called **jossoite.** Its sp. gr. is 5·2; and its hardness 3.

S. H. C. Briggs[26] heated 3·5 grms. of antimony oxychloride, $2SbOCl.Sb_2O_3$, with 6 grms. of chromic trioxide and 6 c.c. of water in a sealed tube for 4 hrs. at 200°. The tube contained a straw-yellow sublimate, and an orange-yellow deposit in spherical, crystalline aggregates, insoluble in water, and slowly soluble in nitric acid—*vide supra*, antimony chromite. The composition approximated *antimony tetroxybischromate*, $3SbO_2.2CrO_3$, or $Sb_3O_4(CrO_4)_2$. Although normal **bismuth chromate,** $Bi_2(CrO_4)_3$, has not been prepared, K. Preis and B. Rayman obtained what they regarded as **potassium bismuth chromate,** $4K_2CrO_4.Bi_2(CrO_4)_3$, by mixing a soln. of 2 mols of bismuth nitrate with a soln. of 9 mols of potassium chromate. The precipitate is non-crystalline. J. Milbauer obtained only a 6·3 per cent. conversion to chromate when a mixture of bismuth oxide or carbonate and chromic oxide was heated to 480° in oxygen at 12 atm. press. A number of basic salts has been reported, with $Bi_2O_3 : CrO_3 : H_2O = 3:1:0$; $3:2:0$; $1:1:0$; $1:2:1$; $5:11:6$; and $3:7:0$. Of these, A. J. Cox recognized only the 1 : 2 : 1-compound—the 1 : 4 : 1-compound may be a basic dichromate. The 5 : 11 : 6-compound, reported by M. M. P. Muir to be formed by the protracted boiling of the 1 : 4 : 1-compound with dil. nitric acid, is considered by A. J. Cox to be an impure 1 : 2 : 1-compound; and a similar remark applies to the 3 : 7 : 0-compound reported by M. M. P. Muir to be formed by heating the 1 : 4 : 1-compound with conc. nitric acid. The other basic salts are supposed to be impure 1 : 2 : 1 or 1 : 4 : 1-compounds or mixtures of these. The results of A. J. Cox's examination of the ternary system: Bi_2O_3–CrO_3–H_2O at 25° are summarized in Fig. 64. If the soln. at 25° has a smaller conc. than 7·80 mols of CrO_3 per litre, the 1 : 4 : 1-compound is hydrolyzed and it passes into the 1 : 2 : 1-compound, which is stable even when the soln. is almost pure water. S. H. C. Briggs did not succeed in making a bismuth chromate—*vide supra*, bismuth chromite.

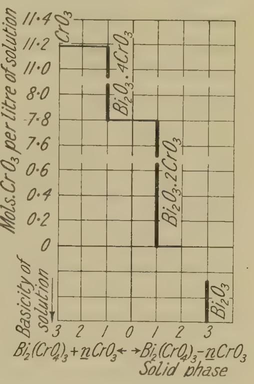


FIG. 64.—Equilibrium Diagram of the Ternary System: Bi_2O_3–CrO_3–H_2O at 25°.

W. Schmid reported the 3 : 1 : 0-compound or $3Bi_2O_3.CrO_3$, which may be **bismuthyl orthochromate,** $(BiO)_6CrO_6$. It is said to be formed by boiling bismuthyl hydroxide with a conc. soln. of potassium chromate. The heavy, pale orange powder is washed with boiling water. It can be heated to redness without decomposition. J. Löwe prepared the 3 : 2 : 0-compound—possibly **bismuthyl paradichromate,** $(BiO)_3{\equiv}CrO{-}O{-}CrO{\equiv}(BiO)_3$—by pouring a soln. of bismuth nitrate, containing as little free nitric acid as possible, into an excess of a soln. of potassium chromate, and washing the product with hot water. W. Schmid obtained it by heating the 1 : 2 : 1-compound with molten potassium nitrate, and leaching the soluble salts from the cold product with water; and M. M. P. Muir, by boiling the 5 : 11 : 6- or the 3 : 7 : 0-compound with potash-lye. A. J. Cox regarded this product as a mixture of bismuth oxide and the 1 : 2 : 1-compound. J. Löwe said that the lemon-yellow, micro-crystalline powder contains only one per cent. of water when dried at 110°. It can be heated to redness without melting or without decomposition. It is insoluble in cold or hot water; it is freely soluble in an excess of dil. hydrochloric or nitric acid, but if the acid be not in excess, the 1 : 2 : 1-compound is formed. When boiled with dil. soda-lye, it forms a bright red basic salt. "Bismuth chromate," said A. Naumann, "is insoluble in acetone."

M. M. P. Muir reported the 1 : 1 : 0-compound, **bismuthyl chromate,** $Bi_2O_3.CrO_3$, or $(BiO)_2CrO_4$, to be formed by treating a soln. of bismuth nitrate with an excess of potassium chromate or dichromate, and, after the addition of a few drops of nitric acid, boiling the mixture for a few hours until it is transformed into a red powder. The product is washed with hot water, and dried at 100°. It is also obtained by boiling the 1 : 2 : 1-compound with a soln. of potassium dichromate and hydroxide. The vermilion-coloured powder consists of microscopic needles. It does not decompose when heated in a crucible over the bunsen-flame, but when strongly heated it becomes dark brown; it is insoluble in water, soluble in dil. hydrochloric acid, but not so soluble in dil. nitric or sulphuric acid. Boiling soda-lye converts part of it into the 3 : 1 : 0-compound, and part is dissolved.

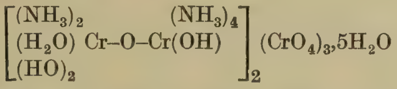
J. Löwe poured a nearly neutral soln. of bismuth nitrate into an excess of a warm soln. of potassium dichromate and boiled the mixture for some time. The product, washed with water and dried at 140°, consisted of $Bi_2O_3.2CrO_3$, or $Bi_2O_3.2CrO_3$, that is, *bismuthyl dichromate*, $(BiO)_2Cr_2O_7$, or **bismuth hydroxychromate,** $Bi(OH)CrO_4$. M. M. P. Muir, W. Schmid, and K. Preis and B. Rayman also prepared this salt. R. W. Pearson obtained a product by a similar process, but regarded it as the 1 : 1 : 0-compound. F. Nolle also prepared a similar salt. A. J. Cox showed that this compound is produced by the hydrolysis of the 1 : 4 : 0-compound—Fig. 64. At 25°, the salt is stable in the presence of water containing not less than 0·00001 mol of chromic acid per litre. J. Löwe obtained it by the action of mineral acids on the 1 : 1 : 0-compound; W. Schmid, by boiling bismuthyl hydroxide with an excess of a soln. of chromic acid; and M. M. P. Muir, by the action of dil. nitric acid on the 1 : 4 : 1-compound. J. Löwe, W. Schmid, and A. J. Cox supposed the salt to be anhydrous; and M. M. P. Muir, hydrated. The anhydrous salt consists of minute, orange-yellow scales, which decompose at a red-heat; and are insoluble in hot or cold water, but soluble in dil. mineral acids.

M. M. P. Muir prepared the 1 : 4 : 1 compound—*bismuth hydroxydichromate*, $Bi_2O_3.4CrO_3.H_2O$, or else **bismuthyl quaterochromate,** $BiO.O.CrO_2.O.CrO_2.O.CrO_2.O.CrO_2.O.BiO$, without combined water—by boiling the 1 : 1 : 0-compound with a little conc. nitric acid. A. J. Cox obtained it by the action of chromic acid on bismuth oxide provided the soln. contains at least 7·8 mols of CrO_3 per litre at 25°—Fig. 64. The salt is washed with a similar soln. of chromic acid. The salt prepared by A. J. Cox was not hydrated; M. M. P. Muir's product was said to be the monohydrate when dried at 100°; but A. J. Cox said that it was not completely dried. M. M. P. Muir found that the water is expelled at 200°–250°. The small ruby-red crystals are monoclinic prisms which decompose when strongly heated, forming a reddish vapour and a green residue. It is insoluble in hot and cold water; but it dissolves freely in mineral acids; with conc. hydrochloric acid, chlorine is evolved. It forms a pale orange product when boiled for a long time with dil. nitric acid.

The **vanadium chromates** have been discussed in connection with the chromium vanadates. According to C. W. Blomstrand,[27] an aq. soln. of columbium oxychloride gives a yellow, granular precipitate of **columbium chromate** when it is treated with potassium chromate.

The so-called **chromium chromates** have been discussed in connection with the oxides Cr_5O_9, or $2Cr_2O_3.CrO_3$; Cr_8O_{15}, or $3Cr_2O_3.2CrO_3$; CrO_2, or $Cr_2O_3.CrO_3$; Cr_4O_9, or $Cr_2O_3.2CrO_3$; Cr_5O_{12}, or $Cr_2O_3.3CrO_3$; and Cr_6O_{12}, or $Cr_2O_3.4CrO_3$. H. J. S. King prepared **chromic hydroxypentamminochromate,** $[Cr(NH_3)_5(OH)]CrO_4$, by the action of the chloride of the base in ammoniacal soln. on ammonium chromate. O. T. Christensen[28] prepared **chromic nitritopentamminochromate,** $[Cr(NH_3)_5(NO_2)]CrO_4$, by treating the corresponding chloride with a cold, sat. soln. of potassium chromate. The salt forms small, yellow crystals, sparingly soluble in water; and they explode like gunpowder when heated. A. Hiendlmayr prepared **chromic fluopentamminochromate,** $[Cr(NH_3)_5F]CrO_4$, by the action of potassium chromate on a soln. of the chloride of the series. S. M. Jörgensen prepared **chromic chloropentamminochromate,** $[Cr(NH_3)_5Cl]CrO_4$, by treating the corresponding chloride or nitrate with potassium chromate, and, after filtration, washing the product with cold water. The microscopic, rhombic plates are soluble in water. P. T. Cleve obtained **chromic aquo-**

chlorotetramminochromate, $[Cr(NH_3)_4)H_2O)Cl]CrO_4$, from a soln. of the corresponding chloride by the addition of potassium chromate. The brownish-black powder decomposes when heated. S. M. Jörgensen obtained **chromic bromopentamminochromate,** $[Cr(NH_3)_5Br]CrO_4$, from a cold sat. soln. of the nitrate by the addition of N-K_2CrO_4. The brownish-red product forms the chloride when treated with hydrochloric acid. He also prepared **chromic oxyaquotrihydroxyhexamminochromate,** $[Cr_2(O_4H_5)(NH_3)_6]_2(CrO_4)_3.5H_2O$, or



$$\left[\begin{array}{l}(NH_3)_2 \qquad\qquad (NH_3)_4\\ (H_2O)\ Cr{-}O{-}Cr(OH)\\ (HO)_2\end{array}\right]_2 (CrO_4)_3,5H_2O$$

by the action of potassium chromate in excess on a soln. of the chloride. The microscopic, reddish-brown, rhombic plates are sparingly soluble in water. P. Pfeiffer and W. Vorster prepared **chromic hexaethylenediaminohexahydroxychromate,** $[Cr_4(OH)_6(en)_6](CrO_4)_3.5H_2O$, from a soln. of the chloride and a conc. soln. of potassium chromate. The brownish-red compound is decomposed by a prolonged boiling with water. W. J. Sell prepared **chromic hexacarbamidochromate,** $[Cr(CON_2H_4)_6](CrO_4)_3.4H_2O$.

J. J. Berzelius[29] obtained a basic **molybdenum chromate** by adding potassium chromate to a soln. of molybdenum chloride; and another basic salt as a precipitate by adding ammonia to a soln. of the dichromate. The pale yellow soln. when spontaneously evaporated furnishes white or yellowish-white acicular or scaly crystals which are efflorescent. A. Atterberg prepared **molybdous tetrabromochromate,** $[Mo_3Br_4]CrO_4$. If a soln. of molybdous tetrabromodihydroxide in alkali-lye be treated with potassium dichromate, no precipitate is formed; but if an acid, say acetic acid, be also added, the soln. becomes dark red, and a dark purple-brown powder is precipitated. The compound decomposes when heated. It is insoluble in dil. acids, but soluble in hot, conc. hydrochloric acid. It is decomposed by alkali-lye; and it is insoluble or sparingly soluble in soln. of alkali chromates. For **tungsten chromates,** see chromium tungstates.

According to H. Moser, and J. J. Berzelius, potassium chromate gives an ochre-yellow precipitate with uranyl nitrate; and C. F. Rammelsberg obtained a precipitate with uranium tetrachloride and potassium chromate—*vide supra,* uranium chromite; while J. F. John observed that a soln. of yellow uranic carbonate in chromic acid deposits red, cubic and dendritic crystals, which fuse with partial decomposition at a red-heat. According to N. A. Orloff, a sat. soln. of uranium trioxide in chromic acid, yields, on evaporation, yellow needles of normal **uranyl chromate,** $(UO_2)CrO_4.3H_2O$. At 15°, 100 parts of water dissolve 7·52 parts of the *trihydrate* forming a pure yellow soln., which, on evaporation at 100°, gives an amorphous, brown mass, soluble in water to a brown soln. Uranyl chromate dissolves slowly in alcohol at the ordinary temp.; this soln. decomposes on boiling, also when exposed to the action of sunlight, with the separation of a brown precipitate. The filtrate from this precipitate when evaporated to dryness yields an amorphous, brown mass, partially soluble in water; it probably consists of a mixture of uranyl chromate and chromous uranate. According to J. Formanek, the *henahydrate,* $(UO_2)CrO_4.11H_2O$, obtained by dissolving the hydroxide in an aq. soln. of chromic acid and concentrating the filtered soln. on the water-bath, crystallizes from boiling water in yellow needles, effloresces on exposure to the air, and loses the whole of its water at 200°; only silver, lead, mercurous, and bismuth salts produce precipitates in its aq. soln. In precipitating chromic acid as mercurous chromate, in presence of uranium salts, the mercurous nitrate employed must be free from oxides of nitrogen, and the soln. must be slightly acidic; otherwise some of the uranium salt is also precipitated. J. Aloy gave −6·3 Cals. for the heat of soln. of a mol of this salt in 1000–2500 mols of water at 18°–20°. According to N. A. Orloff, when potassium chromate is added to an aq. soln. of uranyl chromate, the basic salt, yellow **uranyl oxybischromate,** $UO_3.2UO_2CrO_4.8H_2O$, or

$(UO_2)_3O(CrO_4)_2.8H_2O$, is formed; and if uranyl acetate is similarly treated, **uranyl oxychromate,** $UO_3.UO_2CrO_4.6H_2O$, or $(UO_2)_2O(CrO_4).6H_2O$, is formed. He added that the formation of the basic salts indicates that in soln. uranyl chromate behaves like a mixture of uranic and chromic acids. S. H. C. Briggs obtained a complex, $2UO_3.3CrO_3.2Py$, with pyridine.

J. Formanek observed that yellow plates of **ammonium uranyl chromate,** $(NH_4)_2CrO_4.2(UO_2)CrO_4.6H_2O$, are produced by mixing a soln. of a mol of uranyl nitrate with a soln. of a mol of ammonium chromate, and evaporating the liquor over sulphuric acid; the same salt is obtained by treating ammonium uranate with a warm, conc. soln. of chromic acid, and evaporating the filtered liquid over sulphuric acid. The yellow, monoclinic crystals of the *hexahydrate* have the axial ratios $a:b:c=0{\cdot}8016:1:1{\cdot}0196$, and $\beta=72°\ 31'$. The salt is partially decomposed by boiling water. In some cases, probably owing to a variation of temp., orange-red crystals of a *trihydrate* were formed. J. Formanek obtained **potassium uranyl chromate,** $K_2CrO_4.2UO_2CrO_4.6H_2O$, by a process analogous to that employed for the ammonium salt. The axial ratios of the yellow, monoclinic plates or prisms were $a:b:c=0{\cdot}7566:1:0{\cdot}9714$, and $\beta=107°\ 22'$. The salt is soluble in acidulated water, and it is decomposed by boiling water. J. Wiesner reported a number of complex potassium salts are formed by precipitation from mixtures of uranyl nitrate and potassium chromate, *viz.*, $K_4(UO_2)_3(CrO_4)_5.7H_2O$; $K_6(UO_2)_4(CrO_4)_7.7H_2O$; $K_2(UO_2).(CrO_4)_2.H_2O$; and $K_2Cr_2O_7.3(UO_2)CrO_4.14H_2O$. J. Formanek, H. Bürger, and E. Rimbach obtained yellow crystals of **sodium uranyl chromate,** $Na_2CrO_4.2UO_2CrO_4.10H_2O$, by a process analogous to that employed for the ammonium salt. The salt is freely soluble in water, without decomposition. J. Formanek obtained **silver uranyl chromate** as a vermilion precipitate by treating a soln. of uranyl chromate with silver nitrate. Unlike J. Formanek, B. Szilard was unable to detect any decomposition of silver uranyl chromate in light even after several days' exposure. J. Formanek prepared **mercurous uranyl chromate** in a similar manner; so also **lead uranyl chromate;** and **bismuth uranyl chromate.**

According to J. F. John,[30] an aq. soln. of chromic acid slowly dissolves manganese with the evolution of hydrogen; manganous oxide and carbonate are also dissolved by the acid forming, presumably, soln. of **manganous chromate.** The soln. has an acidic reaction and a pungent, metallic taste, and after repeated evaporation it deposits nearly all the manganese in a higher state of oxidation. T. Thomson said that potassium chromate or dichromate does not give a precipitate with manganous salts immediately, but after some time, especially with the chromate, a brownish-black precipitate is produced. According to U. Antony and U. Paoli, if excess of alkali hydroxide be added to a soln. containing a chromium and a manganese salt in the proportion $Mn:8Cr(O=16)$, no precipitate is obtained, but the liquid is coloured emerald green and must be regarded as a colloidal soln. of the hydroxides of chromium and manganese, since this behaviour is exhibited only when the salts are present in exactly the above ratio. Chromium being tervalent and having both an acid and basic function, whilst manganese is bivalent and decidedly metallic in its properties, it is inferred that they exist in this soln. in the form of a salt, an electrolyte, which must be either a manganous chromite or polychromite. When this liquid is exposed to the air, or, better, when oxygen is passed through it, it quickly turns brown but remains free from precipitate. The element undergoing the oxidation is the manganese which becomes quadrivalent; the *rôles* of the two elements thus become interchanged and a more or less basic chromium manganite is formed. The chromium hydroxide now begins to undergo oxidation and the amount of chromate formed in the soln. increases until about 60 per cent. of the chromium has been converted. Continued action of oxygen has now no further effect on the liquid which, after a time, deposits a dark precipitate of constant composition, the proportion $Mn:Cr$ having the value $1:3$; when this compound is treated with cold dil. sulphuric acid, the chromium dissolves as sulphate whilst the manganese remains in soln. as the hydrate of manganese dioxide.

If now to this liquid is added an alkaline soln. of chromium hydroxide, the latter undergoes immediate and complete oxidation. U. Antony and U. Paoli also measured the speed of the oxidation. R. Warington observed that manganous salts are coloured yellowish-brown by potassium chromate, and in time a dark brown precipitate is formed; which, with dil. soln., may be crystalline **manganous oxychromate,** $MnO.MnCrO_4.2H_2O$, in agreement with the analyses of R. Warington, and H. Reinsch. C. Freese obtained a similar salt from a boiling soln. of manganous sulphate and potassium chromate; and A. J. Fairrie, using manganous chloride, obtained what he regarded as $3Mn_2O_3.Cr_2O_3.3CrO_3.6H_2O$. E. Schulze was unable to obtain a manganous chromate from a cold soln. of manganous carbonate and chromic acid. C. Freese said that the oxychromate loses half its water at 180° and the remainder at 300°; P. Grouvelle, that the salt is slightly soluble in water; and R. Warington, that with potash-lye it furnishes potassium chromate; with hydrochloric acid it gives chlorine; and dissolves in sulphuric or nitric acid forming an orange-yellow liquid. E. Donath described the use of manganese chromate as a pigment *chrome-brown.* C. Hensgen prepared **ammonium manganous chromate,** $(NH_4)_2CrO_4.2MnCrO_4.4H_2O$, as a precipitate from a mixed soln. of manganous and ammonium sulphates. It can be crystallized from a soln. of chromic acid. The bluish-black crystals resemble iodine. It decomposes at 200°, and if the salt be rapidly heated, a slight explosion occurs. The corresponding **ammonium manganous trischromate,** $K_2CrO_4.2MnCrO_4.2H_2O$, was obtained in a similar way, and by varying the proportions of the component salts used in the preparation, intermediate compounds are formed. M. Gröger obtained **potassium manganous bischromate,** $K_2CrO_4.MnCrO_4.2H_2O$, from $4N$-K_2CrO_4 mixed with an equal vol. of N-$MnCl_2$. F. Breinl and J. Klaudy supposed the salt to be monohydrated. According to M. Gröger, the salt is decomposed by water, with the separation of a brown precipitate. It gives an orange-red soln. with sulphuric acid. No definite compound was obtained by using a greater excess of the chromate soln., and with boiling soln. chromium manganite is formed.

It is scarcely to be expected that **ferrous chromate** could be prepared in aq. soln. because of the strongly oxidizing properties of the chromates and chromic acid; L. N. Vauquelin [31] obtained a yellowish-brown precipitate on adding potassium chromate to a soln. of ferrous sulphate. The precipitate gave up no chromic acid to alkali-lye, and formed a green soln. with nitric acid. C. Lepierre found that the product of the action is a basic complex ferric salt—*vide infra.* Neither A. Maus, nor C. W. Eliot and F. H. Storer, were able to prepare normal **ferric chromate.** According to A. Maus, if a soln. of a ferric salt be treated with alkali chromate, a brown powder is formed which is resolved by water into soluble chromic acid, and insoluble ferric oxide. A brown soln. is obtained when hydrated ferric oxide is digested with chromic acid. The soln. is not rendered turbid by dilution with water, or by boiling; and, on evaporation, it yields a brown mass soluble in water and in alcohol. L. A. Wels found the magnetic susceptibility of **potassium ferric chromate,** $K[Fe(CrO_4)_2].2H_2O$, to be $39{\cdot}44\times10^{-6}$ mass unit. The brown product obtained by the action of potassium chromate on a soln. of a ferric salt was found by V. Kletzinsky, and C. W. Eliot and F. H. Storer to have the composition of **ferryl chromate,** $(FeO)_2CrO_4$. L. Blanc also prepared the basic chromate. S. H. C. Briggs obtained ferric oxybischromate, $2Fe_2O_3.4CrO_3.H_2O$, or $(FeCrO_4)_2O.\frac{1}{2}H_2O$, by treating 5 grms. of ferric chloride as in the case of the aluminium salt. The shining black crystals were mixed with a highly coloured, more basic substance. According to C. Hensgen, **ammonium ferric chromate,** $(NH_4)_2CrO_4.Fe_2(CrO_4)_3.4H_2O$, is obtained when the precipitate, produced by mixing conc. soln. of ammonium chromate and ferric chloride, is dissolved in hydrochloric acid, and the soln. slowly evaporated. The dark red, leafy, crystalline mass is rapidly washed with cold water, or with alcohol and ether. It decomposes when heated, or when left in contact with water. C. Lepierre obtained the same salt in red crystals by evaporating a cold soln. of ferric chloride and ammonium dichromate. C. Hensgen obtained **potassium ferric chromate,** $K_2CrO_4.Fe_2(CrO_4)_3.4H_2O$, by a process analogous to that used for the ammonium salt; it is decomposed slowly by water. According to R. Weinland and E. Mergenthaler, when a mixed soln. of ferric nitrate, chromic acid, and ammonia is heated on a water-bath, carmine red, insoluble ammonium ferric chromate, $NH_4[Fe(CrO_4)_2]$, separates; and likewise, under analogous conditions, potassium ferric chromate, $K[Fe(CrO_4)_2].2H_2O$, as a sparingly soluble, dark orange-red, microcrystalline powder. With pyridine under similar conditions, there is formed **pyridine ferric chromate,**

$$\left[Fe(CrO_4)_6\right]\begin{matrix}H_6\\H_3(C_5H_5N)_3\end{matrix}$$

C. Lepierre found that C. Hensgen's salt is produced by the action of ferric chloride with a large excess of potassium dichromate; if ferric chloride be in excess, potassium chlorochromate is one of the products; if neither salt is in excess, ruby-red crystals of the basic salt *potassium ferric oxyseptieschromate,* $2K_2CrO_4.Fe_2(CrO_4)_3.FeO(CrO_4)_2.7H_2O$, are formed; and if the one soln. is allowed to diffuse into the other, anhydrous crystals of *potassium ferric trioxysexieschromate,* $3K_2CrO_4.Fe_2O_3.Fe_2(CrO_4)_3$, are produced. A sat. soln. of potassium chromate when added to an excess of a sat. soln. of ferric chloride yields ruby-red hexagonal crystals of *potassium ferric dioxyundecieschromate,* $4K_2CrO_4.2Fe_2(CrO_4)_3.(FeO)_2CrO_4$; with an excess of chromate, an orange-yellow precipitate of *potassium ferric trioxynovieschromate,* $6K_2CrO_4.Fe_2O_3.Fe_2(CrO_4)_3.nH_2O$, is formed—*hexahydrate,* if washed with alcohol, and the *decahydrate* if washed with water; with only a slight excess of ferric salt, *potassium ferric pentoxydecieschromate,* $6K_2CrO_4.Fe_2O_3(FeO)_2CrO_4.Fe_2(CrO_4)_3$. In all cases, in hot soln., the products are mixtures. If a soln. of 6 mols of ferrous sulphate and 2 mols of potassium chromate be allowed to react at 0°, *potassium ferric enneadecaoxybischromate,* $3K_2O.6Fe_2O_3.2CrO_3$, is formed. It is washed with water, alcohol, and ether at 0°; when moist, it is brown, and when dried, black. After drying in the air, it retains about 30 per cent. of water. The action of ferrous sulphate on potassium chromate at higher temp. yields only basic ferric sulphates. The action of excess of potassium chromate on ferrous sulphate yields a yellowish-brown, micro-crystalline precipitate of *potassium ferric enneaoxyquaterchromate,* $4K_2CrO_4.3Fe_2O_3$, which retains 22·7 per cent. of water when dried in air. If ammonium ferrous sulphate be employed, the precipitate is *potassium ferric pentadecaoxydecieschromate,* $7K_2CrO_4.Fe_2(CrO_4)_3.5Fe_2O_3$. If ferric chloride be employed with sodium chromate, *sodium ferric oxyquinquieschromate,* $4Na_2CrO_4.6Fe_2O_3.(FeO)_2CrO_4$, is formed; and with ammonium chromate, *ammonium ferric pentadecaoxysexieschromate,* $6(NH_4)_2CrO_4.5Fe_2O_3$. If ammonium and sodium dichromates are employed, immediate oxidation occurs without forming basic chromates. It is not to be supposed that these basic salts are all chemical individuals.

Potassium chromate with soln. of cobalt salts gives a reddish-brown precipitate which is probably a basic salt. F. J. Malaguti and M. Sarzeau[32] represented it as **cobaltous dioxychromate,** $2CoO.CoCrO_4.4H_2O$, or $3CoO.CrO_3.4H_2O$. S. H. C. Briggs obtained **cobaltous chromate,** $CoCrO_4$, by heating a soln. of the carbonate in chromic acid in a sealed tube at 260° for several hrs. The greyish-black crystals are readily soluble in dil. nitric acid. The *dihydrate,* $CoCrO_4.2H_2O$, is obtained in bronze coloured prisms or leaflets, when soln. of cobalt acetate and potassium chromate are mixed. The salt is always contaminated with some double chromate. F. de Boer studied the X-ray spectrum. N. Parravano and A. Pasta obtained yellow needles of *cobaltous bisethylenediaminochromate,* $CoCrO_4.2C_2H_4(NH_2)_2$. C. Freese said that **cobaltous oxychromate,** $CrO.CoCrO_4.2H_2O$, appears as a reddish-brown precipitate when boiling soln. of a cobaltous salt and potassium chromate are mixed. One mol. of water is expelled at about 220°, and the other at about 300°. The dehydrated salt slowly takes up water again from moisture. M. Gröger dissolved cobalt carbonate in the cold soln. of an eq. amount of N-CrO_3. The filtrate is evaporated, and when the residue is taken up with water there remains the brownish-black *monohydrate* of cobaltous oxychromate. F. J. Malaguti and M. Sarzeau found that when the dioxychromate is treated with ammonia it forms orange-yellow needles, and an amorphous, ruby-red product.

O. W. Gibbs and F. A. Genth, and C. D. Braun treated cobaltic hexamminonitrate with potassium chromate and obtained a yellow precipitate of **cobaltic hexamminochromate,** $[Co(NH_3)_6]_2(CrO_4)_3.5H_2O$. O. W. Gibbs and F. A. Genth,

C. D. Braun, and T. Klobb also prepared **cobaltic hexamminochlorochromate,** $[Co(NH_3)_6]Cl(CrO_4)$ with $1\frac{2}{3}$ and with 3 mols. of water. G. Vortmann treated an aq. soln. of cobaltic chloroaquotetramminochloride with potassium dichromate and obtained **cobaltic octamminochromate,** $Co_2(NH_5)_8(CrO_4)_3.4H_2O$. The brown precipitate furnishes bronze brown plates of the *tetrahydrate* when recrystallized from dil. acetic acid. If potassium chromate be used as precipitant, the olive-green *decahydrate* is formed. According to S. H. C. Briggs, if a cobaltic diaquotetrammino-salt is added to a large excess of neutral sodium chromate, dark chocolate-brown cobaltic octamminochromate, $Co_2(CrO_4)_3.8NH_3.2\frac{1}{2}H_2O$, is formed, and this furnishes the monohydrate, if kept in vacuo. A. Hiendlmayr prepared **cobaltic fluopentamminochromate,** $[Co(NH_3)_5F]CrO_4$, by the action of potassium chromate on a soln. of the fluoride of the series. O. W. Gibbs prepared **cobaltic nitritopentamminochromate,** $[Co(NH_3)_5NO_2]CrO_4.H_2O$, as a yellow precipitate by adding potassium chromate to the corresponding nitrate. J. N. Brönsted and A. Petersen found its molar solubility at 20° to be $S=0{\cdot}000258$ and in the presence of various salts of molar conc. C,

	C	0·02	0·05	0·10	0·20	0·50	1·0
S	H.COOK	$0{\cdot}0_3361$	$0{\cdot}0_3481$	$0{\cdot}0_3636$	$0{\cdot}0_3816$	$0{\cdot}0_21212$	$0{\cdot}0_21787$
	H.COONa	$0{\cdot}0_3323$	$0{\cdot}0_3410$	$0{\cdot}0_3558$	$0{\cdot}0_3746$	$0{\cdot}0_21131$	$0{\cdot}0_21729$
	NaCl	—	$0{\cdot}0_3425$	$0{\cdot}0_3565$	$0{\cdot}0_3785$	—	—

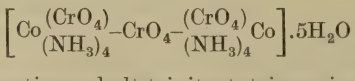
They also studied *cobaltic isothiocyanatopentamminochromate,* $[Co(NH_3)_5SCy]CrO_4$; and *cobaltic tetrathiocyanatodiamminochromates*; P. R. Ray prepared **cobaltic thiosulphatopentamminochromate,** $[Co(NH_3)_5(S_2O_3)]_2CrO_4$, by adding potassium chromate to the corresponding chloride. S. M. Jörgensen obtained, in an analogous manner, yellow, microscopic needles of **cobaltic cis-dinitritotetramminochromate,** $[Co(NH_3)_4(NO_2)_2]_2CrO_4$, and O. W. Gibbs, **cobaltic trans-dinitritotetramminochromate.** S. M. Jörgensen likewise obtained **cobaltic nitratopentamminochromate,** $[Co(NH_3)_5NO_3]CrO_4$, in ochre-yellow or brick-red octahedral crystals; also brick-red, microscopic crystals of **cobaltic chloropentamminochromate,** $[Co(NH_3)_5Cl]CrO_4$; and likewise greyish-brown, rosetted needles of **cobaltic chloroaquotetramminochromate,** $[Co(NH_3)_4(H_2O)Cl]CrO_4$; and brown, six-rayed aggregates of **cobaltic bromopentamminochromate,** $[Co(NH_3)_5Br]CrO_4$.

S. H. C. Briggs added a soln. of a cobaltic diaquotetrammino-salt to a large excess of an alkali chromate and obtained a series of alkali bischromatotetramminocobaltiates, $M'[Co(CrO_4)_2(NH_3)_4]$. A green form corresponds with the trans-configuration, and a brown form with the cis-configuration of the chromate radicles. The formation of the brown form is favoured by the presence of a large proportion of dichromate in the soln. The salts obtained were **lithium cis-bischromatotetramminocobaltiate,** $Li[Co(CrO_4)_2(NH_3)_4].1\frac{1}{2}H_2O$; **sodium trans-bischromatotetramminocobaltiate,** $Na[Co(CrO_4)_2(NH_3)_4]$, as a green, microcrystalline powder; and the corresponding **sodium cis-bischromatocobaltiate,** $Na[Co(CrO_4)_2.(NH_3)_4].H_2O$, in greenish-brown crystals; and **potassium trans-bischromatotetramminocobaltiate,** $K[Co(CrO_4)_2(NH_3)_4]$. If magnesium chromate be employed, **magnesium cisbischromatotetramminocobaltiate,** $Mg[Co(CrO_4)_2(NH_3)_4]_2.2H_2O$, is formed in brown crystals, and also **magnesium trans-bischromatotetramminocobaltiate,** $Mg[Co(NH_3)_4(CrO_4)_2]_2.8H_2O$, which, when dehydrated in vacuo over sulphuric acid, gives the *hexahydrate.* The *octohydrate* is thought to be $Mg[Co(NH_3)_4(CrO_4)_2(H_2O)_2]_2.4H_2O$, in which the co-ordination number of the cobalt atom is eight. If a cobaltic diaquotetrammino-salt be added to a large excess of neutral ammonium chromate, dark reddish-brown crystals of **ammonium chromatopentamminobischromate,**

$(NH_4)_2[Co(CrO_4)(NH_3)_5](CrO_4)_2$, are formed. With sodium chromate, the octammine is formed as indicated above.

M. Gröger prepared ammonium **cobaltous oxyquaterochromate,** $(NH_4)_2CrO_4.CoO.3CoCrO_4.3H_2O$, by the action of 2 vols. of N-$CoCl_2$ on one vol. of N-$(NH_4)_2CrO_4$. On allowing the precipitate to stand in contact with the mother-liquor for some time, dark brownish-red microscopic crystals are formed. The composition is different if other proportions of the constituent salt soln. are mixed. S. H. C. Briggs prepared **ammonium cobaltous chromate,** $(NH_4)_2CrO_4.CoCrO_4.6H_2O$, in brownish-yellow prisms, by adding a soln. of 30 grms. ammonium chromate in 60 c.c. of water to a soln. of 40 grms. crystallized cobalt acetate in 120 c.c. of water and cooled by ice and salt. The salt can be kept for some days at 8°, but it gradually darkens in colour, and loses water; decomposition is rapid at 20°. M. Gröger prepared **ammonium cobaltous diamminoquaterochromate,** $(NH_4)_2CrO_4.3CoCrO_4.2NH_3.3H_2O$, from cobaltous chloride and ammonium chromate. The dark brown product is decomposed by water and by heat. M. Gröger prepared brown **potassium cobaltous chromate,** $K_2CrO_4.CoCrO_4.2H_2O$, from a soln. of one vol. of $3N$-$CrCl_2$ and 3 vols. of $3N$-K_2CrO_4; and the basic salt **potassium cobaltous oxyquaterochromate,** $K_2CrO_4.CoO.3CoCrO_4.3H_2O$, or $HO.Co.CrO_4.Co.KCrO_4(H_2O)$, by mixing 2 vols. of N-$CoCl_2$ and one vol. of N-K_2CrO_4; or one vol. of the former and 2 vols. of the latter. The dark reddish-brown product consists of microscopic crystals, which are soluble in cold, dil. sulphuric acid, and are decomposed by water forming cobaltous dioxychromate. S. H. C. Briggs prepared **cæsium cobaltous chromate,** $Cs_2CrO_4.CoCrO_4.6H_2O$, as a brown crystalline powder, by mixing 2 grms. of cæsium chromate in 6 c.c. of cold water with a soln. of 1·2 grms. of crystalline cobalt acetate cooled to about —5°.

S. H. C. Briggs prepared a series of **chromatocobaltammines**—*e.g.* **cobaltic chromatopentamminonitrate,** $[Co(NH_3)_5(CrO_4)]NO_3$, by the action of potassium chromate on the aquopentamminonitrate. The salt is moderately soluble in cold water, and the freshly prepared soln. is not precipitated by silver, barium, or lead salts, but precipitation occurs at once in the boiling soln. Similarly, cobalt aquopentamminochloride furnishes brownish-red crystals of **cobaltic chromatopentamminochloride,** $[Co(NH_3)_5(CrO_4)]Cl$. If the mother-liquor is heated to 50° and treated with more potassium chromate, on cooling, it furnishes yellowish-brown prisms of **cobaltic chloropentamminochromate,** $[Co(NH_3)_5Cl)]CrO_4.2\frac{1}{2}H_2O$. If cobaltic chromatopentamminochloride in water at 60° be treated with silver chromate, **cobaltic chromatopentamminochromate,** $[Co(NH_3)_5(CrO_4)]_2CrO_4.3H_2O$, is formed in scaly crystals the colour of silver chromate. P. R. Ray and P. V. Sarkar represented it as a dihydrate, and obtained it by the action of ammonium dichromate and aq. ammonia on freshly precipitated cobalt hydroxide. By treating cobaltic diaquotetramminonitrate with a dil. soln. of potassium chromate, **cobaltic chromatotetramminonitrate,** $[Co(NH_3)_4(CrO_4)_2]NO_3.\frac{1}{2}H_2O$, was formed as a dark reddish-brown crystalline mass, soluble in water; if an excess of potassium chromate is used, **cobaltic chromatotetramminochromate,** $[Co(NH_3)_4(CrO_4)_2]CrO_4.3H_2O$, is formed as a brown crystalline powder. The corresponding dichromate (*q.v.*) was also prepared. By treating cobalt diaquotetramminonitrate with a conc. soln. of potassium chromate, a greenish precipitate of **cobaltic trichromatotetrammine,** $[Co(NH_3)_4(CrO_4)_2]CrO_4.5H_2O$,



$$\left[Co\begin{matrix}(CrO_4)\\(NH_3)_4\end{matrix}-CrO_4-\begin{matrix}(CrO_4)\\(NH_3)_4\end{matrix}Co\right].5H_2O$$

was obtained; and by treating cobalt trinitratotriammine with a soln. of potassium chromate, **cobaltic hydroxychromatotriammine,** $[Co(NH_3)_3(OH)(CrO_4)_2].2H_2O$, was formed—for the dichromate, *vide infra.*

According to R. Tupputi,[33] a soln. of chromic acid dissolves nickel hydroxide or carbonate forming a yellow soln. which deposits a powder soluble in a large excess of the acid. The soln. deposits a non-deliquescent mass of red crystals, which, according to J. F. John, are resolved at a red-heat into chromic and nickel oxides. If the soln. be treated with nickel carbonate, or with alkali-lye, R. Tupputi observed that a reddish-yellow insoluble powder of a **nickel oxychromate** is deposited; and H. Stokes, and F. J. Malaguti and M. Sarzeau observed that a basic salt is deposited when a soln. of nickel sulphate is mixed with potassium chromate. C. Freese added that the yellowish-brown product is scarcely attacked by cold potash-lye, but all the chromium is extracted by boiling lye. F. J. Malaguti and M. Sarzeau represented its composition by $4NiO.CrO_3.6H_2O$; C. Freese, by $3NiO.CrO_3.3H_2O$; and E. A. Schmidt obtained precipitates ranging from $3NiO.CrO_3.6H_2O$ to $2NiO.CrO_3.6H_2O$ by varying the conc. of the soln. employed. S. H. C. Briggs said that while nickel chromate is insoluble in water, it is not precipitated from nickel salt soln., and it must therefore be polymerized. It is formed by heating nickel carbonate and a soln. of chromic acid in a sealed tube at 260°. The black crystals of **nickel chromate,** $NiCrO_4$, are washed with water, alcohol, and ether. They are insoluble in hot dil. nitric acid, and are slowly attacked by conc. nitric acid or aqua regia. G. L. Clark found that **nickel hexamminochromate,** $Ni(NH_3)_6CrO_4$, has a vap. press. of 760 mm. at 408°.

S. H. C. Briggs obtained **ammonium nickel chromate,** $(NH_4)_2CrO_4.NiCrO_4.6H_2O$, by adding a soln. of ammonium chromate to a soln. of a nickel salt; and M. Gröger obtained it by adding $3N$-$(NH_4)_2CrO_4$ to half its vol. of N-$NiCl_2$, and allowing the mixture to stand for some time. The green crystals can be recrystallized from water at 40° without change. G. L. Clark studied the relations between the at. vol. and the stability. S. H. C. Briggs showed that when treated with ammonia, **ammonium nickel diamminochromate,** $(NH_4)_2CrO_4.NiCrO_4.2NH_3$, is formed. The product loses water and ammonia when it is heated, and it decomposes suddenly between 200° and 300°. M. Gröger obtained the basic salt, **ammonium nickel dihydroxyquaterchromate,** $3(NH_4)_2CrO_4.Ni(OH)_2.NiCrO_4$, from a mixture of a cold, sat. soln. of ammonium chromate with a fifth of its vol. of $3N$-$NiCl_2$. The yellowish-brown crystals are stable in air; they are decomposed by water with the separation of a basic nickel chromate; and form with water a yellowish-green soln. which when evaporated at a low temp. yield ammonium chromate, and ammonium nickel chromate. M. Gröger mixed $3N$-Na_2CrO_4 with half its vol. of N-$NiCrO_4$ and obtained a brown, amorphous precipitate, probably a basic sodium nickel chromate; and by mixing $3N$-K_2CrO_4 with half its vol. of N-$NiCrO_4$, a reddish-brown precipitate is formed which, when allowed to stand under its mother-liquor, becomes crystalline **potassium nickel chromate,** $K_2CrO_4.NiCrO_4.2H_2O$. This *dihydrate* is stable in air, and loses no water on the water-bath. It is decomposed by water with the separation of a basic salt. S. H. C. Briggs obtained the *hexahydrate* by adding 8 grms. of potassium chromate in 14 c.c. of water to 8 grms. of nickel acetate in 27 c.c. of water at —6°. The yellowish-green crystals dissolve in water with decomposition. The hexahydrate forms isomorphous mixtures with the corresponding sulphate. S. H. C. Briggs also prepared **rubidium nickel chromate,** $Rb_2CrO_4.NiCrO_4.6H_2O$; and **cæsium nickel chromate,** $Cs_2CrO_4.NiCrO_4.6H_2O$, in an analogous way. Both salts are decomposed by water.

The normal chromates of the platinum metals have not been prepared. According to T. Thomson,[34] a soln. of hydrochloroplatinic acid, when treated with potassium chromate furnishes a dark red precipitate containing potassium chloroplatinate. P. T. Cleve, and G. B. Buckton found that an ammoniacal soln. of platinous tetramminodichromate furnishes a yellow powder consisting of microscopic tablets of **platinous tetramminochromate,** $[Pt(NH_3)_4]CrO_4$. The same salt is formed by precipitation from a soln. of platinous chloride by potassium chromate. P. T. Cleve prepared **platinic dinitratotetramminochromate,** $[Pt(NH_3)_4(NO_3)_2]CrO_4$, by treating the corresponding chloride with potassium chromate and drying the product at 100°. The lemon-yellow product detonates sharply when heated; it is insoluble in water. He also prepared **platinic dichlorotetramminochromate,** $[Pt(NH_3)_4Cl_2]CrO_4$, in an analogous manner from the corresponding nitrate. So also with **platinic hydroxysulphatotetramminochromate,** $[Pt(NH_3)_4(OH)(SO_4)]CrO_4.2H_2O$; and with **platinic hydroxychlorotetramminochromate,** $[Pt(NH_3)_4(OH)Cl]CrO_4$. S. G. Hedin prepared **platinic sulphatotetrapyridinochromate,** $[Pt(C_5H_5N)_4(SO_4)]CrO_4.6H_2O$; and C. Enebuske, **platinic chromatobisethylsulphide,** $Pt\{(C_2H_5)_2S\}_2CrO_4$.

§ 16. The Dichromates

H. Moser,[1] Y. T. Gerassimoff, and others obtained **ammonium dichromate,** $(NH_4)_2Cr_2O_7$, by evaporating a soln. of chromic acid half sat. with ammonia. Y. T. Gerassimoff said that double decomposition with ammonium chloride and sodium dichromate gives an impure product. S. Darby, J. S. Abel, and J. S. Abel and H. Richmond showed that if the chromic acid is contaminated with sulphuric acid, that salt is easily freed from that contamination by recrystallization. R. Segalle obtained ammonium dichromate by heating an ammoniacal soln. of a mol of potassium dichromate until the liquid has a garnet-red colour; and then evaporating for crystallization. F. A. H. Schreinemakers' observations on the equilibrium conditions are summarized in Fig. 29. Analyses were reported by S. Darby, M. Gröger, M. Siewert, J. Schabus, and J. S. Abel and H. Richmond.

The yellowish-red crystals were found by C. F. Rammelsberg to be monoclinic prisms with the axial ratios $a : b : c = 1\cdot0271 : 1 : 1\cdot7665$, and $\beta = 93^\circ 42'$. The (101)-cleavage is clear, and the (010)-cleavage incomplete. Observations on the crystals were also made by H. J. Brooke, J. Schabus, and A. J. Weiss. G. N. Wyrouboff noted some resemblances between the crystals and those of triclinic potassium dichromate; but the two salts are not isomorphous. B. Gossner and F. Mussgnug found that the X-radiograms showed that the monoclinic crystals have a cell with $a = 7\cdot78$ A., $b = 7\cdot54$ A., and $c = 13\cdot27$ A., with $\beta = 93^\circ 42'$. Unit cell contains 4 mols. A. Duffour said that the crystals are isomorphous with the monoclinic form of potassium dichromate. H. Schiff gave 2·367 for the sp. gr.; F. W. Clarke, and G. N. Wyrouboff, 2·150; and E. Moles and F. Gonzalez, 2·16 at 25°. K. F. Slotte found the sp. gr. of soln. of ammonium dichromate with 6·85, 13·0, and 19·93 per cent. of the dichromate to be respectively 1·0393, at 12°, 1·0782 at 10·5° and 1·1258 at 12°; and the viscosities (water 100) to be respectively 98·9, 99·1, and 100·6 at 10°; 76·8, 78, 80·2, at 20°; 62·5, 63·9 and 66·4 at 30°; and 51·9, 53·3, and 55·7 at 40°. H. Moser, and E. Jäger and G. Krüss said that the salt is stable in air; and J. S. Abel and H. Richmond, that it is stable at 100°. A. Maus, R. Böttger, E. Moles and F. Gonzalez, and A. A. Hayes found that the salt decomposes at a temp. below redness leaving a residue of chromic oxide. The reaction is attended by the emission of light, and may be by a feeble detonation, especially, as shown by M. Siewert, if it be quickly heated in a test-tube. The gaseous products of the reaction were found by J. S. Abel and H. Richmond, and A. Levy to be nitrogen and water, but S. Darby observed that some ammonia gas may be produced; and M. Siewert, and W. M. Hooton, some nitric oxide and oxygen. C. N. Hinshelwood and E. J. Bowen studied the rate of decomposition at 219°. W. C. Ball said that at 185°–205° the salt darkens in colour, and decomposes slowly with the evolution of water, nitrogen, and ammonia; and after six days' heating, there remains a black residue approximating $3CrO_2.H_2O$; and if the heating be interrupted when the salt is half decomposed, an insoluble black product, approximating $Cr_2O_3.2CrO_3.2NH_3.H_2O$, is obtained. W. M. Hooton found that if ammonium dichromate be heated in air, below the inflammation temp. 190°, the end-product has the composition $2CrO_2.H_2O$; and if heated in the absence of oxygen, $H_2Cr_2O_4$—*vide supra* for E. Maumené's observations on ammonium chromate. E. Moles and F. Gonzalez observed that tranquil decomposition occurs at about 225°, and that the oxidation of the "ammonium" to nitrogen is most complete where the reaction occurs most rapidly. The black residue thereby obtained is chromium peroxide. Y. T. Gerassimoff found that the aq. soln. is slightly decomposed when it is boiled.

R. Böttger said that if an intimate mixture of the dichromate with half its weight of picric acid be brought in contact with a glowing splint, it decomposes with sparking forming pale green, flocculent chromic oxide. C. N. Hinshelwood and E. J. Bowen studied the rate of the thermal decomposition of ammonium dichromate. With the explosive decomposition of the salt, M. Berthelot found that 7·8 Cals. are developed; and he gave for the heat of formation: $2H_2CrO_4(800_{aq.}) + 2NH_4OH(1600_{aq.}) = (NH_4)_2Cr_2O_{7aq.} + 24$ Cals at 12°; E. Moles and F. Gonzalez, 23·275 Cals., and F. Morges, 26·988 Cals. at 19·5°. M. Berthelot gave for the reaction $(NH_4)_2Cr_2O_{7aq.} + 2NH_4OH_{aq.} = 2(NH_4)_2CrO_{4aq.} + 20\cdot4$ Cals.; for precipitated chromic oxide, $2Cr(OH)_3 + 2NH_4OH_{aq.} + 3O = (NH_4)_2Cr_2O_{4aq.} + 34\cdot6$ Cals. at 12°; and 47

Cals. with the solid dichromate; $(NH_4)_2CrO_{4\text{solid}}+CrO_{3\text{solid}}=(NH_4)_2Cr_2O_{7\text{solid}}+11\cdot300$ Cals. For the heat of decomposition, $(NH_4)_2Cr_2O_7=Cr_2O_3+N_2+4H_2O+(78\cdot000+Q)$ cals., where Q denotes the heat of transformation of chromic oxide. For the reducing action of ammonia on chromium trioxide: $2CrO_3+2NH_3=Cr_2O_3+3H_2O_{\text{gas}}+N_2+146\cdot6$ Cals.; the heat of soln. of a mol of the salt in 560 mols of water at 13° is $-12\cdot44$ Cals.; E. Moles and F. Gonzalez gave $-12\cdot904$ Cals.; P. Sabatier gave $-5\cdot8$ Cals. for the heat of soln. of a mol of the salt in 200 mols of water. P. Sabatier measured the absorption spectrum. S. Schlivitch observed a photovoltaic effect with soln. of ammonium dichromate and platinum electrodes. H. Moser said that the aq. soln. has a saline taste, and reddens litmus. The salt is less soluble than ammonium chromate. E. Moles and F. Gonzalez gave for the solubility 23·88 per cent. at 16°, and 28·63 per cent. at 25°. F. A. H. Schreinemakers found that 100 grms. of water at 30° dissolve 47·17 grms. of ammonium dichromate. The salt in aq. soln. is less hydrolyzed than the monochromate, and Y. T. Gerassimoff found that the solubilities of ammonium dichromate, S grms. of salt per 100 grms. of water, working on cooling and heating systems, are:

		0°	20°	40°	60°	80°	100°
S	Cooling .	18·40	36·0	58·7	86·0	—	—
	Heating .	18·13	35·3	58·4	86·0	115·0	155·6

and the disturbance is probably due to undercooling. The solubility curves for the system $(NH_4)_2Cr_2O_7$–$(NH_4Cl)_2$–H_2O at different temp., are summarized in Fig. 65—mols of salt per 1000 mols of water; *confer* Fig. 1, **1**. 11, 1. A. Naumann and A. Rücker calculated that in a N-soln. at the b.p., 0·0108 per cent. is hydrolyzed. B. Reinitzer said that the salt is soluble in absolute alcohol. W. P. Jorissen discussed the limits of the reaction of ammonium dichromate with potassium chloride and sulphate.

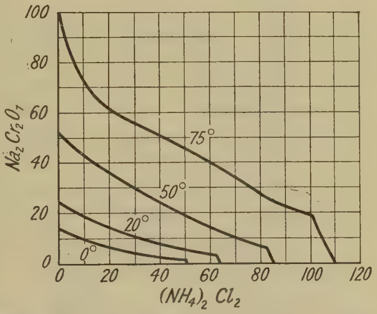

FIG. 65.—The Effect of Ammonium Chloride on the Solubility of Ammonium Dichromate.

According to C. F. Rammelsberg,[2] if chromic acid or nitric acid be added to a soln. of lithium chromate, the liquid furnishes deliquescent crystals of **lithium dichromate,** $Li_2Cr_2O_7.2H_2O$. The conditions of equilibrium are illustrated by Fig. 31. The black plates have curved surfaces. L. Schulerud found that the water of crystallization is completely lost at 130°, and the salt melts at a higher temp. with the evolution of oxygen. The salt can be recrystallized from water without decomposition; and F. A. H. Schreinemakers observed that 100 grms. of water at 30° dissolve 130·4 grms. of $Li_2Cr_2O_7$. A. Heydweiller found the sp. gr., and eq. conductivity, at 18°, to be:

	0·2N-	0·5N-	N-	2N-
Sp. gr. . .	1·01581	1·03928	1·0780	1·1540
λ . . .	73	66·1	58·7	47·7

The preparation of **sodium dichromate,** $Na_2Cr_2O_7.2H_2O$, is effected by methods similar to those employed for the potassium salt. J. d'Ans and J. Löffler[3] observed it amongst the products of the action of sodium hydroxide on chromic oxide. M. Siewert said that it is not produced by partially saturating sodium chromate with nitric acid, but it is produced by dissolving sodium chromate in a slight excess of chromic acid, and evaporating the liquid over sulphuric acid in vacuo. G. Bessa discussed the manufacture of sodium dichromate. R. Kissling found that commercial samples contained 83·79 to 92·84 per cent. $Na_2Cr_2O_2$; and with seven different samples, 23 days' exposure resulted in the absorption of 60 per cent. of water in each case. B. Neumann and C. Exssner discussed the conversion of sodium chromate to dichromate in aq. soln. by carbon dioxide under press.

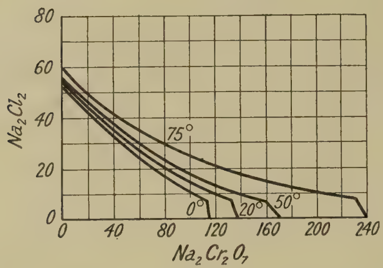

FIG. 66.—The Effect of Sodium Chloride on the Solubility of Sodium Dichromate.

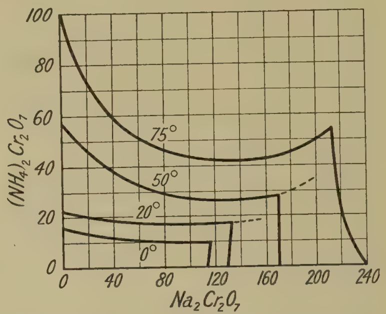

FIG. 67.—The Effect of Ammonium Dichromate on the Solubility of Sodium Dichromate.

E. Müller and E. Sauer found that in the conversion of soln. of sodium chromate to dichromate and hydroxide by electrolysis, if the anolyte is a soln. of sodium chromate and the catholyte one of sodium hydroxide the yield is less than if sodium chromate is used in both compartments. A. Lottermoser and K. Falk found that better yields are obtained with three compartment cells with sodium chromate in all three compartments rather than with sodium hydroxide as catholyte and sodium chromate in the other two compartments. This is because in the former case circumstances are least favourable for the migration of HO-ions into the anode compartment. I. Stsherbakoff studied the electrolysis of soln. of sodium chromate using a mercury cathode. T. W. Richards and G. L. Kelley found that sodium dichromate can be readily purified from potassium salts and sulphates by recrystallization from water a number of times. The conditions of equilibrium, worked out by F. A. H. Schreinemakers, are illustrated by Fig. 34. F. Mylius and R. Funk gave 83° for the transition temp. from the *dihydrate* to the anhydrous salt. The solubility, *S* per cent., of sodium dichromate in water is :

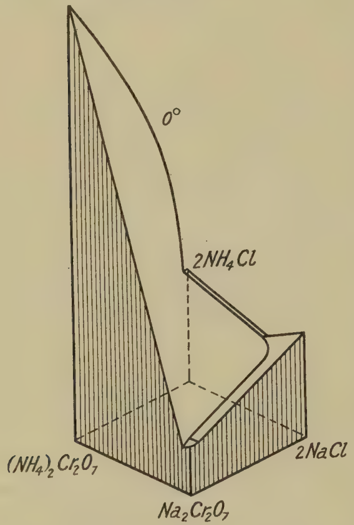

FIG. 68.—The Quaternary System : $(NH_4)_2Cr_2O_7$–$Na_2Cr_2O_7$–Na_2Cl_2–$(NH_4Cl)_2$ at 0°.

	0°	10°	20°	40°	60°	80°	83°	93°	98°
S .	62·0	63·0	64·3	68·8	73·9	79·4	80·7	81·20	81·24
Solid phase	$Na_2Cr_2O_7.2H_2O$						$Na_2Cr_2O_7$		

A. Stanley found that 100 parts of water dissolve 107·2 parts of $Na_2Cr_2O_7$ at 0° ; 109·2 parts at 15° ; 116·6 parts at 30° ; 142·8 parts at 80° ; 162·8 parts at 100° ; and 209·7 parts at 139°. F. A. H. Schreinemakers found that at 30° water dissolves 66·4 per cent. of $Na_2Cr_2O_7$. Y. I. Gerassimoff found that the solubility curves for the system $Na_2Cr_2O_7$–NaCl–H_2O, at different temp., are summarized in Fig. 66—mols of salt per 100 mols of water—*confer* Fig. 1, **1**. 11, 1. The solubility curves for the system $(NH_4)_2Cr_2O_7$–$Na_2Cr_2O_7$–H_2O, at different temp., are summarized in Fig. 67—mols of salt per 1000 mols of water—*confer* Fig. 1, **1**. 11, 1. The equilibrium diagrams for the quaternary systems $(NH_4)_2Cr_2O_7$–$Na_2Cr_2O_7$–Na_2Cl_2–$(NH_4Cl)_2$, at 0° and 75° are indicated in Figs. 68 and 69.

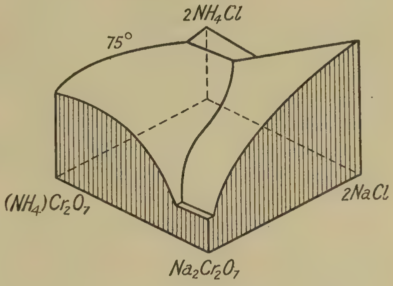

FIG. 69.—The Quaternary System: $(NH_4)_2Cr_2O_7$–$Na_2Cr_2O_7$–Na_2Cl_2–$(NH_4Cl)_2$ at 75°.

The dihydrate furnishes hyacinth-red, thin, six-sided prisms which, according to M. Siewert, are triclinic, but, according to L. Münzing, are monoclinic. G. N. Wyrouboff gave for the axial ratios of the monoclinic crystals $a:b:c=0{\cdot}5698:1:1{\cdot}824$, and $\beta=94°\ 55'$; while L. Münzing gave $0{\cdot}5912:1:0{\cdot}5698$, and $\beta=85°\ 5'$. The optic axial angle $2V=83°\ 54'$; and the optical character is positive. The deliquescent crystals were found by A. Stanley to have a sp. gr. 2·5246 at 13°. According to A. Stanley, the sp. gr. of the aq. soln. is:

$Na_2Cr_2O_7$.	1	5	10	20	30	40	50 per cent.
Sp. gr. . .	1·007	1·035	1·071	1·141	1·208	1·280	1·343

while H. C. Jones and H. P. Basset gave at 18°,

$Na_2Cr_2O_7$.	1·31	2·59	5·09	7·50	9·83	18·40	26·90 per cent.
Sp. gr. . .	1·0096	1·0190	1·0377	1·0568	1·0756	1·1491	1·2285

L. J. Simon measured the viscosities of soln. of sodium dichromate—*vide supra*, potassium chromate. F. Mylius and R. Funk observed that a soln. sat. at 18° contains 63·92 per cent. of $Na_2Cr_2O_7$, and has a sp. gr. 1·745; F. Rüdorff found that the salt does not decompose when in aq. soln. I. Traube found the drop-weight of the molten anhydrous salt to be 262·0 mgrms. A. Stanley found that the dihydrate becomes anhydrous above 303°; it melts at 320°, and decomposes at 400° with the evolution of oxygen. P. L. Robinson and co-workers observed no transition phenomenon when the salt is cooled between 300° and 70°. H. C. Jones and H. P. Bassett found that soln. with 0·1, 0·2, and 0·4 mols per litre lower the f.p. of water respectively 0·490°, 0·946°, and 1·872°. A. Stanley said that the sat. aq. soln. boils at 139°. J. Thomsen gave for the heat of formation: $2H_2CrO_4(800_{aq.})+2NaOH(400_{aq.})=Na_2Cr_2O_{7aq.}+26{\cdot}268$ Cals. at 18°; and F. Morges, $2H_2CrO_{4aq.}+2NaOH_{aq.}=Na_2Cr_2O_7+26{\cdot}076$ Cals. at 19·5°.

H. Dufet found the indices of refraction of the crystals of the dihydrate to be $\alpha=1{\cdot}7510$, $\beta=1{\cdot}6994$, and $\gamma=1{\cdot}6610$ for the D-line. P. Walden measured the electrical conductivity of aq. soln. at 25°; while H. C. Jones and co-workers found for the molar conductivity, μ mho, and for the percentage ionization, α, calculated from μ/μ_∞, with a mol of the salt in v litres of water:

	v . . .	8	16	32	128	512
μ	0° . .	92·18	96·57	101·25	106·8	106·1
	15° . .	136·5	143·5	148·4	158·3	158·3
	25° . .	—	176·3	182·7	194·7	194·4
	35° . .	—	211·4	219·5	233·5	234·6
α	0° . .	87·5	91·3	95·7	100·0	100·0
	35° . .	—	89·9	93·3	100·0	100·0

H. C. Jones calculated from the sp. gr., f.p., and conductivity data that soln. with M mols per litre have H mols of water in combination with a mol of the salt, when M is 0·1, 0·2, 0·3, and 0·4, H is respectively 20·5, 9·7, 6·5, and 7·9. A. Poirot found that the emission of anodic rays with purified sodium dichromate is regular and stable. The emission starts suddenly below the m.p. of the salt. The anode is surrounded by a yellowish glimmer. There is an intense yellow spot on the cathode where it is hit by the anodic rays. The spectra of the anodic and cathodic lights were examined. H. Ollivier studied Verdet's constant, and the paramagnetism of the salt. E. C. Franklin and C. A. Kraus said that the salt is insoluble in liquid ammonia; A. Naumann, that it is insoluble in acetone; and B. Reinitzer that 100 c.c. of a soln. in alcohol contain 5·13 grms. of $Na_2Cr_2O_7.2H_2O$. The alcoholic soln. decomposes rapidly. V. K. la Mer and C. L. Read found that the reaction between sodium hydroxide and dichromate is unimolecular with respect to the dichromate and the velocity constant is k=529 per min., and the heat of reaction 15,320 cals. per mol of dichromate. The results are best interpreted as involving the reactions: $Cr_2O_7'' + H_2O \rightleftharpoons 2HCrO_4'$ (slow), with $Q=-13,640$ cals. per mol $Cr_2O''_7$; $HCrO_4' \rightleftharpoons H^{\cdot} + CrO_4''$ (rapid), with $Q=780$ cals. per mol $HCrO_4'$; and $H^{\cdot} + OH' = H_2O$ (rapid).

The manufacture of **potassium dichromate,** $K_2Cr_2O_7$, has been discussed in connection with the extraction of chromium from chromite, etc. F. Tassaert[4] obtained it by mixing soln. of chromic acid and potassium hydroxide in such proportions that the soln. reacts neither acidic nor alkaline, and evaporating the liquid. The dichromate first separates out, and the mother-liquid, then reacting alkaline, furnishes the monochromate. It is also obtained from acidified soln. of potassium chromate. E. Gray, and V. S. Yatloff also described its preparation. The conditions of equilibrium have been studied by F. A. H. Schreinemakers, F. Flöttmann, and I. Koppel and E. Blumenthal, and the results are summarized in Figs. 36 to 41. Y. R. Goldstein, and H. Pincass discussed the transformation from chromate to dichromate by carbon dioxide; and I. Obreimoff and W. J. de Haas, the colour changes at low temp. The bright-red, rectangular, four-sided tabular or prismatic crystals are triclinic pinacoids which, according to J. Schabus, have the axial ratios $a:b:c=0·5575:1:0·5511$, and $\alpha=82° 0'$, $\beta=90° 51'$, and $\gamma=83° 47'$. The (010)-cleavage is perfect; and the (100)- and the (001)-cleavages are distinct. G. N. Wyrouboff also made some crystallographic observations. B. Gossner and F. Mussgnug showed that the X-radiograms of the triclinic salt correspond with a unit cell having 4 mols., and $a=7·50$ A., $b=7·38$ A., and $c=13·40$ A., whilst $\alpha=82° 0'$, $\beta=96° 13'$, and $\gamma=90° 51'$. H. Dufet observed that the optical character is positive; and that the optic axial angles $2E=98° 58'$ and $2V=51° 53'$ for the D-line; and $2V=52° 24'$ for the Li-line. A. Beer observed that the crystals are pleochroic. H. Baumhauer studied the corrosion figures. A. Schubnikoff showed that a crystal, suspended in a slighly supersaturated soln. rotating on a horizontal axis, grows so that the (001)-face is bright and smooth, while the $(00\bar{1})$-face is dull and rough, while the other parallel faces are not the same size or are absent. This is taken to show that the crystals of the dichromate belong to the asymmetric class of the triclinic system. A. Hettich and A. Schleede made observations on the crystals. E. Pietsch and co-workers found that the attack on the crystals by sulphuric acid begins at the corners and edges. D. N. Artemeéff, R. Marc, M. le Blanc and W. Schmandt, H. Jeannel, M. Kimura, and C. Tomlinson studied the growth of crystals in supersaturated soln. The rate of growth of the crystals is not solely a diffusion phenomenon as is the case with the speed of dissolution—*vide infra.* H. A. Miers said:

> If a drop of strong soln. of potassium dichromate, placed upon a microscope-slide, be observed under the microscope as it crystallizes, and if the drop be sufficiently thin, it will generally be found that the following events take place: The first crystals make their appearance at the edges of the drop and after growing rapidly for a short period as branching fibres, they begin to grow quietly in the form of plates or flattened rods presenting the characteristic form of the crystals of this substance. These crystals continue to grow uniformly, but after a short period, at a distance from the growing crystals, and at some spot where the drop is thin, a fresh crystalline growth starts suddenly from a point, and extends with great rapidity in all directions in the form again of branching needles and fibres. After a short period this rapid growth ceases and each of the fibres swells out at the end into a well-defined crystal and continues to grow slowly and uniformly as a single, regular plate. The process may be repeated by the sudden development of a new spontaneous growth in another portion of the drop, and the same succession of events may be repeated again and again. Sometimes these successive growths constitute a series of

rings approximately parallel to the edges of the drop which follow one another till the centre of the drop is reached.

An illustration of a drop of the dichromate in the act of crystallization is shown **1**. 11, 3, Fig. 11. The phenomenon connected with crystallizations in labile and metastable soln.—**1**. 9, 6, Fig. 14—gave a possible explanation for the periodic crystallization of soln. of potassium dichromate. E. Pietsch and co-workers studied the attack at the corners and edges of the crystals by conc. sulphuric acid, and by an ethereal soln. of hydrogen dioxide. W. von Behren and J. Traube studied the phenomenon attending the dissolution and crystallization of the salt. E. S. Hedges obtained spiral forms of rhythmic crystallization ; and E. N. Gapon studied the rate of crystallization.

Crystals appear at the edge of the drop where, owing to evaporation or cooling, the soln. is sufficiently strong to be in the labile condition, and proceed as rapidly growing fibres ; but so soon as these have by their growth reduced the strength of the soln. in their neighbourhood to the metastable state they continue to grow quietly and uniformly ; presently, however, at some point sufficiently distant from the growing crystals to be also in the labile state, crystallization starts afresh, either spontaneously or perhaps through inoculation by a crystalline speck falling into the drop from the air. This again proceeds as the rapid, fibrous growth, characteristic of the labile condition, until again the liquid passes into the metastable state and the growth is slow.

Soln. with 17·266 (28·5°), 20·00 (32·2°) and 29·09 (43·5°) grms. of salt in 100 parts of water, and sat. at the temp. named, were labile respectively at 18·5°, 22°, and 34°. M. Volmer and A. Weber discussed the formation of nuclei in undercooled soln. C. Decharne observed the crystallization of the dichromate from a soln. mixed with gum, when under the influence of a strong magnetic field. G. Brügelmann said that potassium dichromate forms isomorphous mixtures with pentahydrated cupric sulphate, but J. C. G. de Marignac did not agree. S. F. Schemtschuschny studied the formation of isomorphous mixtures with potassium chloride ; and C. F. Rammelsberg, P. Groth, L. Stibing, A. Sella, A. Fock, H. le Chatelier, and C. von Hauer, solid soln. with potassium pyrosulphate. C. von Hauer observed that the crystals of the dichromate take up potassium sulphate when that salt is present in the liquid during the crystallization.

Triclinic potassium dichromate may be called the α-form ; there is also a monoclinic β-form. E. Mitscherlich observed that when the molten dichromate is slowly cooled, crystals are formed which afterwards decrepitate ; O. Lehmann showed that the change is reversible ; G. Tammann found that there is a large change in vol. at 240°, accompanied by an imperceptible thermal change ; G. Tammann and Q. A. Mansuri measured the rate of crystallization of the powdered salt and found that it commences at 160° with particles over 1 mm. diam., at 166° with particles between 1·0 and 0·3 mm., and at 158·5°–163° with particles smaller than 0·3 mm., and G. N. Wyrouboff concluded that potassium dichromate exists in three forms : (i) a monoclinic form stable near the m.p. ; (ii) a triclinic form stable at the ordinary temp. ; and (iii) a second triclinic form stable in a narrow range of temp. between the other two forms. S. F. Schemtschuschny added that the transition temp., $\alpha\text{-}K_2Cr_2O_7=\beta\text{-}K_2Cr_2O_7$, is 236° ; and P. L. Robinson and co-workers gave 236·8°. P. L. Robinson and co-workers added that the salt separates from the fused state in a compact mass of dark brownish-red, tabular crystals with marked reduction in volume. On further cooling, the crystals change to a loose, orange-red powder. The existence of G. N. Wyrouboff's second triclinic form has not been confirmed, so that the crystals which first separate from the cooling liquid are doubly refracting—probably monoclinic, and at about 236° these crystals pass into the ordinary triclinic form. O. Hauser and H. Herzfeld observed that when hot, conc. soln. of potassium dichromate and hot potassium thiocyanate are mixed, the dichromate crystallizes on cooling in yellowish-brown, doubly-refracting, monoclinic plates. The sp. gr. of this form is 2·10, whereas that of the ordinary triclinic variety is 2·67. The monoclinic dichromate is unstable, and is transformed into the triclinic salt when kept in contact with its sat. soln., or in moist air. It seems probable that this form of the potassium salt is isomorphous with monoclinic ammonium dichromate. A. Duffour also observed that if a considerable excess of aluminium sulphate is added to a soln. of potassium monochromate, some aluminium hydroxide is precipitated, and when the soln. is concentrated by heat, potassium dichromate separates out in monoclinic and triclinic crystals. The monoclinic crystals are isomorphous with those of rubidium and ammonium dichromates. P. L. Stedehouder and P. Terpstra found for the monoclinic form $a:b:c=1{\cdot}0123:1:1{\cdot}7675$, and $\beta=88° 4{\cdot}5'$; and the optic axial angle of the pleochroic crystals $2V=66° 14'$. The X-radiograms gave $a=7{\cdot}42$ A., $b=7{\cdot}35$ A., $c=12{\cdot}97$ A., and $\beta=91° 55°$, with 4 mols. per unit cell which is face-centred on the (100)-side. According to A. Duffour, the axial ratios for the three forms are $a:b:c=1{\cdot}0167:1:1{\cdot}7716$, and $\beta=91° 55'$ for $K_2Cr_2O_7$; $1{\cdot}0202:1:1{\cdot}8081$, and $\beta=98° 28{\cdot}5'$ for $Rb_2Cr_2O_7$; and $1{\cdot}0271:1:1{\cdot}7663$, and $\beta=93° 42'$ for $(NH_4)_2Cr_2O_7$. Although the monoclinic crystals of the dichromate are the unstable form, they exhibit false equilibrium, and can be kept in contact with triclinic crystals in the cold without any appreciable change. They dissolve in a soln. saturated with respect to triclinic crystals at 12·5°, whereas triclinic crystals are unaffected under the same conditions. On heating, the monoclinic crystals decrepitate, and then behave like the triclinic crystals. The following description of potassium dichromate refers to the stable, triclinic forms unless stated otherwise. A. Duffour, and A. F. Hallimond discussed the isodimorphism of potassium and ammonium dichromates; H. E. Buckley, the effect of dichromates on the crystallization of sodium chlorate.

C. J. B. Karsten gave 2·603 for the sp. gr. of potassium dichromate; J. Schabus, 2·689; L. Playfair and J. P. Joule, 2·692 at 3·9°; and H. Schiff, 2·721. H. G. F. Schröder gave 2·702 for that which had been melted, 2·751 for that which had been melted and disintegrated, and 2·702 for the powdered salt. P. Kremers, and G. T. Gerlach gave for the sp. gr. of soln. at 19·5°/19·5°:

$K_2Cr_2O_7$.	1	3	5	7	9	11	13	15 per cent.
Sp. gr. .	1·867	1·022	1·037	1·050	1·065	1·080	1·097	1·110

F. Flöttmann gave for the sp. gr. at 15°, 20°, and 25°, respectively, 1·0635, 1·0768, and 1·0916. For A. Heydweiller's observations, *vide infra*. J. A. Ewing and J. G. MacGregor gave for soln. with 0·99, 2·44, 4·76, and 7·69 per cent. $K_2Cr_2O_7$ the respective values 1·0069, 1·0172, 1·0345, and 1·0561 at 10°/4°; and F. Fouqué gave for soln. with 5·9 grms. of $K_2Cr_2O_7$ per 1000 grms. of water 1·0045 at 0°/4°; 1·0037 at 16·4°/4°; 1·9812 at 75·5°/4°; and 1·9651 at 99°/4°; for soln. with 37·3 grms. of salt per 1000 grms. of water, 1·0257 at 0°; 1·0234 at 19·6°; 1·0030 at 69·6°; and 0·9843 at 99°; and for soln. with 89·2 grms. of salt per 1000 grms. of water, 1·0635 at 16°; 1·0349 at 79°; and 1·0221 at 99·5°. Observations on the sp. gr. were also made by E. F. Anthon, R. L. Datta and N. R. Dhar. R. Lorenz and W. Herz studied the critical density of this and related salts. J. N. Rakshit studied the contraction which occurs when potassium dichromate is dissolved in water, and in ethyl alcohol. K. F. Slotte found the sp. gr. of soln. of potassium dichromate with 4·71 and 6·97 per cent. $K_2Cr_2O_7$ to be respectively 1·0325 at 11°, and 1·0493 at 10·6°; and the viscosities (water 100) respectively 98·9, and 98·6 at 10°; 76·2 and 76·9 at 20°; 61·7 and 62 at 30°; and 51·1 and 51·4 at 40°. A. Kanitz gave for $2N$-, $4N$-, and $8N$-soln. the respective viscosities 1·0061, 1·0034, and 0·9999 (water unity) at 25°. L. J. Simon measured the viscosity of soln. of the salt—*vide supra*, potassium chromate. I. Traube gave 235·9 mgrms. for the drop-weight of the molten salt. R. Lorenz and W. Herz gave 123·6 for the surface tension at the b.p., and 140·6 at the m.p. R. Lorenz and H. T. Kalmus gave for the viscosity η in C.G.S. units:

	397°	417°	437°	457°	477°	497°	507°
η .	0·1339	0·1187	0·1059	0·0938	0·0823	0·0715	0·0664

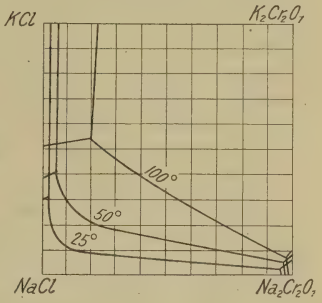

FIG. 70.—Reciprocal Salt Pair : $K_2Cr_2O_7+2NaCl=2KCl+Na_2Cr_2O_7$.

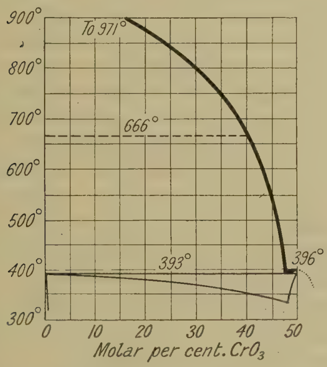

FIG. 71.—Freezing-point Curve of Mixtures of $K_2Cr_2O_7$–KCl.

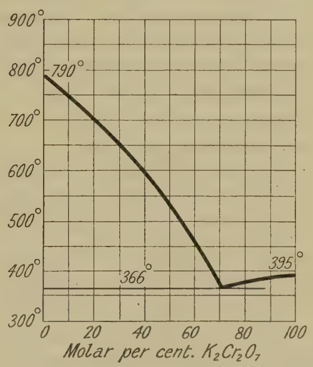

FIG. 72.—Freezing-point Curve of Mixtures of $KCrO_4$–CrO_3, or of $K_2Cr_2O_7$–K_2CrO_4.

F. Rüdorff found that the salt in aq. soln. diffuses through a membrane without dissociation. According to T. Sabalitschka and G. Kubisch, when soln. of potassium dichromate are dialyzed, the ratio K : Cr outside the dialyzer is not constant but is greater than 1. Chromic acid dialyzed more quickly than potassium chromate. Hence, it was inferred that potassium dichromate is partly decomposed into normal chromate and trichromate in dil. aq. soln. : $2K_2Cr_2O_7 \rightleftharpoons K_2CrO_4+K_2Cr_3O_{10}$. L. Playfair and J. P. Joule found the coeff. of thermal expansion—cubical—of the salt to be 0·0122 between 0° and 100°. F. E. Neumann gave 0·1857 for the sp. ht. ; while H. Kopp gave 0·186 between 21° and 52° ; H. V. Regnault, 0·186 between 16° and 98° ; and P. Nordmeyer and A. L. Bernoulli, 0·1386 between —186° and 20°. T. Thomson observed that the dichromate decrepitates when heated, and melts at a temp. much below redness, forming a transparent, red liquid, which on cooling solidifies to a red fibrous mass, which falls to pieces spontaneously—*vide supra.* C. Schubert, and W. Hempel and C. Schubert, observed that the evolution of gas sets in at 500°, and has not ceased as the temp. is raised to 1500° ; the reaction is represented $4K_2Cr_2O_7=3O_2+2(Cr_2O_3.2K_2CrO_4)$. A. Eucken and G. Kuhn gave 0·00395 to 0·00417 for the sp. ht. of large crystals at —190° ; and at 0°, 0·00428 to 0·00429. S. F. Schemtschuschny found that the stable form at the higher temp. has the m.p. 395° ; E. Groschuff gave 396° ; H. S. Roberts, 397·5° ; and P. L. Robinson and co-workers gave 398·4°±0·5°. S. F. Schemtschuschny found that the m.p. diagram of mixtures of potassium chloride and dichromate has two branches meeting at the eutectic 366° and 27·5° molar per cent. of the chloride—Fig. 71. Solid soln. are formed only on the dichromate side of the curve, these contain about 25 molar per cent. of chloride. Sections viewed under the microscope have the uniform structure of solid soln. only when taken from the dichromate side of the eutectic, those on the chloride side show crystals of chloride embedded in the groundwork of the eutectic mixture. J. B. Robertson studied the equilibrium diagram for the system $Na_2Cr_2O_7+2KCl \rightleftharpoons K_2Cr_2O_7+2NaCl$ at 25°, 50°, and 100° ; the results are plotted in Fig. 70. Potassium dichromate and sodium chloride are the compatible salt pair at all temp. ; as the temp. increases the areas on the diagram representing potassium and sodium chlorides increase considerably at the expense of the area representing potassium dichromate. The sodium dichromate area is always very small. E. Groschuff found that the f.p. curve of mixtures of potassium chromate and dichromate falls regularly from the m.p. of the chromate at 971° to the eutectic at 393° and 99 per cent. of dichromate, and it then rises to 396° the m.p. of the dichromate. At the transition temp., $\alpha\text{-}K_2CrO_4 \rightleftharpoons \beta\text{-}K_2CrO_4$, 666°, the mixture contains about 75·5 per cent. of dichromate—Fig. 72. E. Groschuff's attempts to obtain the f.p. curve of mixtures of potassium chromate with over 50 molar per cent. of chromic acid were not successful owing to the decomposition of the chromic acid—Fig. 72. Potassium dichromate suffers considerable decomposition when heated to the m.p. of the monochromate. P. Grouvelle observed that at a high temp. potassium dichromate decomposes into potassium chromate, chromic oxide, and oxygen.

M. Amadori studied the m.p. of mixtures of potassium dichromate with the dimolybdate and the ditungstate. The f.p. of $0{\cdot}5M$- and $0{\cdot}1M\text{-}K_2Cr_2O_7$ is found by R. Abegg and A. T. Cox to be respectively —0·27° and —0·49°; I. Koppel and E. Blumenthal gave —0·63° for the f.p. of a sat. soln. having 4·5 grms. of salt per 100 grms. of water. This is the cryohydric or eutectic temp. for which F. Guthrie gave —0·7° with $0{\cdot}18M$-soln., and C. M. Guldberg, —0·8° with $0{\cdot}15M$-soln. M. S. Sherrill found the lowering of the f.p. of very dil. soln., and calculated the ionization factor i—**1**. 10, 15—to be:

$K_2Cr_2O_7$	$0{\cdot}0005M$-	$0{\cdot}001M$-	$0{\cdot}00510M$-	$0{\cdot}1234M$-	$0{\cdot}02053M$-
F.p. .	—0·00362°	—0·00706°	—0·0350°	—0·070°	—0·113°
i .	3·9	3·8	3·70	3·07	2·98

$K_2Cr_2O_7$.	$0{\cdot}03004M$-	$0{\cdot}05340M$-
F.p. . .	—0·158°	0·263°
i . .	2·84	2·66

The first two sets of determinations quoted are by T. G. Bedford. The fact that the factor i in dil. soln. approaches to 4 means that not only is the molecule $K_2Cr_2O_7$ ionized into three ions $K_2Cr_2O_7 \rightleftharpoons 2K^{\cdot} + Cr_2O_7''$, but that the acid residue is also hydrolyzed: $Cr_2O_7'' + H_2O \rightleftharpoons 2HCrO_4'$. H. G. Leopold and J. Johnston found the mol. lowering of the vap. press. of soln. containing 0·4, 0·6, and $1{\cdot}0M\text{-}K_2Cr_2O_7$ to be respectively 0·0498, 0·0472, and 0·0419. P. Kremers gave 104° for the b.p. of a sat. soln.; M. Alluard gave 103·4° at 718 mm. press.; and I. Koppel and E. Blumenthal, 104·8° for a soln. with 108 grms. of salt per 100 grms. of water. A. Speransky found that the vap. press., p mm., of sat. soln. of the dichromate between 30·06° and 54·75° can be represented by $p=K\{(\theta—77{\cdot}407)/\theta\}^{50}$, where $\log K=7{\cdot}89408$. R. Lorenz and W. Herz studied some relations between the b.p. and the critical temp. W. Herz gave 29·8 Cals. for the heat of fusion per gram. J. G. F. Druce discussed the creeping of the salt during evaporation. M. Berthelot gave for the heat of formation, $(2H_2CrO_{4aq.}, 2KOH_{aq.})$=27·2 Cals. at 8°; 26·8 Cals. at 12°; 26·4 Cals. at 18°; P. Sabatier gave 27·0 Cals. at 17°; and F. Morges, 24·982 Cals. at 19·5°. M. Berthelot also gave $(2CrO_{3aq.}, 2KOH_{aq.})$=43·8 Cals. at 12°; and $(2CrO_{3solid}, 2KOH_{solid})$=106·8 Cals. at 12°; $(2Cr(OH)_3, 2KOH_{aq.}, 3O) = K_2Cr_2O_{7aq.}$+37·8 Cals. at 8°, and with $K_2Cr_2O_{7solid}$, 54·8 Cals. at 8°; and with KOH_{solid} and $K_2Cr_2O_{7solid}$, 113·0 Cals. at 8°; $(K_2CrO_{4solid}, CrO_{3solid})$=15·0 Cals., and $K_2Cr_2O_7$(12 litres of water)+4KOH(8 litres of water)=$2K_2CrO_{4aq.}$+23·6 Cals. at 12°; while P. Sabatier gave 23·0 Cals. at 17°. H. Rose said that the dichromate dissolves in water with a feeble absorption of heat. For the heat of soln., T. Graham gave —17·08 Cals.; F. Morges gave for a mol of the salt in 825 mols of water —17·169 Cals. at 19·5°; J. Thomsen, with 400 mols. of water, —16·7 Cals. at 18°; and with 653·5 mols of water, M. Berthelot gave —17·02 Cals. at 11·6°, or —17·02–6(θ—15) Cals. at θ°. E. von Stackelberg gave for a mol of $K_2Cr_2O_7$ at 17·5° with n mols of water:

n . . .	∞		1000		500		250		167
Heat of solution	18,400		17,440		16,885		16,335		16,000 cals.
Heat of dilution		960		555		550		335	

H. Dufet gave for the indices of refraction of the triclinic crystals α=1·7202, β=1·7380, and λ=1·8197 for the Na-line; and β=1·7209 for the Li-line; and P. L. Stedehouder and P. Terpstra gave for the pleochroic monoclinic crystals α=1·715, β=1·762, and γ=1·892. F. Fouqué found for the refractive indices, μ, with the D-line with soln. of 5·9 grms. of $K_2Cr_2O_7$ in 1000 grms. of water:

	9·0°	17·8°	50·0°	60·0°	70·0°	80·0°	93·2°
μ . .	1·3357	1·3350	1·3305	1·3289	1·3269	1·3259	1·3216

with soln. of 37·3 grms. $K_2Cr_2O_7$ per 1000 grms. of water:

	6·8°	16·0°	50·0°	60·0°	70·0°	80·0°	92·5°
μ . .	1·3413	1·3405	1·3340	1·3340	1·3322	1·3300	1·3270

and with soln. of 89·2 grms. of $K_2Cr_2O_7$ per 1000 grms. of water:

	16·8°	40·0°	50·0°	60·0°	70·0°	80·0°	95·4°
μ . .	1·3508	1·3476	1·3459	1·3441	1·3420	1·3397	1·3360

F. Flöttmann gave for soln. sat. at 15°, 20°, and 25° the values 1·35028, 1·35345, and 1·35685 for the D-line. J. Wagner, E. Viterbi and G. Krauz, A. Lallemand, E. Forster, K. Vierordt, P. Bary, B. K. Mukerji and co-workers, and R. L. Datta and N. R. Dhar made observations on this subject; and M. G. Mellon studied the colour of the soln. J. H. Gladstone gave for the equivalent refraction with the μ-formula, 79·9. The extinction coeff. of 0·03399M-$K_2Cr_2O_7$ for light of wave-lengths λ=508·6$\mu\mu$, 520·9$\mu\mu$, 536$\mu\mu$, and 546·1$\mu\mu$ are respectively 2·12, 0·976, 0·246, and 0·117. L. R. Ingersoll found Verdet's constant for the **electromagnetic rotatary power** for light of wave-length 0·6, 0·8, 1·0, and 1·25μ to be 0·0108, 0·0064, 0·0042, and 0·0025 respectively for soln. of sp. gr. 1·085. The **absorption spectrum** was studied by P. Sabatier, A. Étard, O. Knoblauch, F. Grünbaum, K. S. Gibson, H. C. Jones and W. W. Strong, T. Aden, N. R. Tawde and G. R. Paranjpe, G. Jander, J. Formanek, W. Böhlendorff, H. Bremer, F. Melde, G. Rössler, J. Müller, J. M. Hiebendaal, H. Settegast, and C. P. Smyth. I. Plotnikoff and M. Karsulin observed that the absorption of light by potassium dichromate begins at 595$\mu\mu$, and extends towards the ultra-violet. The photochemical absorption begins at 595$\mu\mu$ in the yellow, reaches a maximum at 500$\mu\mu$ in the green, and then decreases to about 240$\mu\mu$. According to C. Schaefer and M. Schubert, the ultra-red reflection spectrum of potassium dichromate has three maxima, one at 18·12μ, and complex ones at 12·14μ to 13·22μ, and at 10·44μ to 11·1μ. A. E. Lindh, D. Coster, and O. Stelling studied the **X-ray spectra**. H. von Halban and K. Siedentopf, and J. B. Ferguson discussed the potassium dichromate and molybdenum nitrate light filter. H. M. Vernon estimated the degree of ionization of aq. soln. of the salt from the colour. I. Plotnikoff, and M. Schwarz studied the photochemical oxidation of organic compounds by dichromates and chromates—*vide supra*, chromium trioxide. A. Reychler observed that in darkness there is no perceptible action between potassium iodide, and dichromate, and eosin in aq. soln., but in light iodine is liberated. A. Kailan found that an aq. soln. of potassium dichromate is reduced at the rate of 3×10^{11} mol per second by exposure to radium rays. R. Hunt thought that actinized soln. of potassium dichromate produce precipitates of chromates of a different colour from those obtained from soln. made and kept in the dark. F. Bush showed that the difference is due to the difference in the rate of mixing the soln., and not an effect of actinization—*vide supra*, silver chromate. T. Svensson studied the change in the conductivity, and potential of soln. of potassium dichromate in sulphuric acid when exposed to light. W. Herz gave $2{\cdot}42\times10^{12}$ for the vibration frequency. A. Kailan found that the salt is decomposed by exposure to radium radiations. E. Montignie observed that potassium dichromate, after exposure to ultra-violet light, affects a photographic plate.

J. A. Fleming and J. Dewar found that the dielectric constant of water with some potassium dichromate in soln. is not much affected, and similarly at −185°.

W. Schneider observed no piezoelectric effect. R. Lorenz and H. T. Kalmus found the sp. electrical conductivity of the fused salt to be:

	397°	417°	437°	457°	477°	497°	507°
Sp. cond.	0·1959	0·2381	0·2745	0·3109	0·3473	0·3837	0·4019 mho.

Observations on the conductivity of aq. soln. were made by R. Lenz, M. S. Sherrill, P. Walden, and J. Lundberg. A. Heydweiller found for 0·1*N*-, 0·2*N*-, and 0·5*N*-soln., the respective values 0·01010, 0·02012, and 0·05005 for the sp. gr. at 18°, and 98·2, 93·1, and 85·4 for the eq. electrical conductivities. H. C. Jones and C. A. Jacobson observed the mol. conductivity, μ mho, between 0° and 35°, and A. P. West and H. C. Jones between 35° and 65° when a mol of the salt is dissolved in v litres:

v		8	16	32	128	512	1024	2048
μ	0°	116·3	128·7	137·5	152·6	190·6	204·9	214·6
	10°	153·7	171·1	184·2	204·5	260·8	280·5	294·3
	25°	216·9	243·0	262·9	297·0	384·0	420·5	441·7
	35°	261·7	294·5	319·9	365·3	475·4	522·8	553·4
	65°	352·9	—	396·9	417·9	426·8	—	448·9
α	0°	54·2	60·0	64·1	71·1	88·8	95·5	100·0
	35°	47·3	53·2	57·8	66·0	85·9	94·5	100·0
	65°	78·6	—	88·4	93·1	95·1	—	100·0

The calculated values for the percentage ionization, α, are also indicated. W. C. D. Whetham gave for the eq. conductivity, λ mho, with soln. containing *N*-gram-equivalents per litre at 0°:

N	0·00001	0·0001	0·001	0·01	0·1	0·2
λ	81·3	76·3	71·4	70·4	64·3	61·5

and inferred from the small rise in conductivity with increasing dilution soln. of medium conc., and a larger change with soln. of small conc., that in the former case the ionization proceeds $Cr_2O_7'' + H_2O \rightleftharpoons 2HCrO_4'$, and in the latter case $HCrO_4' \rightleftharpoons H^{\cdot} + CrO_4''$. E. Spitalsky found the $H^{\cdot}$-ion conc., from observations on the effect of the dichromate soln. on the velocity of hydrolysis of diazoacetic ether, to be 0·000259 with soln. containing 0·1012 mol of $K_2Cr_2O_7$ per litre, and 0·000188 with soln. containing 0·0664 mol per litre. W. V. Bhagwat and N. R. Dhar found that the salt exists in aq. soln. probably as $KHCr_2O_4$. G. P. Vincent studied the depolarizing action of acidic soln. of the dichromate on hydrogen liberated at a smooth platinum electrode. T. Murayasu studied the conductivity of soln. in glycine. W. Spring observed that soln. of dichromate, on standing, slowly change their colour, and their electrical conductivity; this means that there is a slow change in the condition of the soln.—*vide supra*, potassium chromate, and chromic acid. H. Buff observed that on electrolysis of the molten salt, oxygen is evolved at the anode; and F. Morges added that the dichromate is reduced to chromate at the cathode—*vide supra*. For the photochemical action of light, *vide* chromic acid. S. Schlivitch observed a photovoltaic effect with soln. of potassium dichromate and platinum electrodes. F. Weigert studied the electrolytic reduction of soln. of the dichromate. J. B. Johnson discussed the e.m.f. due to the thermal agitation of a soln. of the dichromate.

G. Meslin said that potassium dichromate is paramagnetic. He found that the magnetic susceptibility of the powder is $0·13\times10^{-6}$ mass unit; and G. Quincke gave for a soln. of the dichromate between 18° and 20°, $0·76\times10^{-6}$ mass unit. J. Forrest measured the variations in the parallel and transverse components of the magnetization of the crystals. P. Weiss and P. Collet found the paramagnetism of a soln. of the dichromate is constant between 14° and 50°; and the subject was discussed by P. Weiss, L. A. Welo and A. Baudisch, and S. Berkman and H. Zocher. W. G. Hankel and H. Lindenberg found that the crystals exhibit pyroelectricity in that when warmed the (001)-face is usually positively electrified, and the (00$\bar{1}$)-face negatively electrified—the reverse behaviour is rare.

T. Thomson said that potassium dichromate has a cooling, bitter, metallic taste ; it is stable in air, and is not hygroscopic. V. Ipatieff and A. Kisseleff found that when $2N$-$K_2Cr_2O_7$ with some conc. sulphuric acid is exposed to hydrogen at 180° to 200 atm. press., a crystalline compound, $K_2O.Cr_2O_3.Cr_2(SO_4)_3.H_2O$, is formed. It is insoluble in acid, and is dissolved by molten sodium carbonate and potassium nitrate. H. P. Cady and R. Taft found potassium dichromate to be appreciably soluble in phosphoryl chloride, and very slightly soluble in liquid sulphur dioxide. According to C. F. Cross, in an atm. sat. with moisture, a mol of the salt takes up 3·5 mols of water which is removed by pressing it between filter-papers. Observations on the solubility of potassium dichromate in water were made by T. Thomson, H. Moser, M. le Blanc, M. Alluard, P. Kremers, M. S. Sherrill, A. Michel and L. Krafft, and H. G. Greenish and F. A. U. Smith. The following observations on the percentage solubility, S, are due to I. Koppel and E. Blumenthal for temp. below 100°, and to W. A. Tilden and W. A. Shenstone for temp. above 110° :

	−0·63°	0°	30°	60°	104·8°	117°	148°	180°
S . .	4·31	4·43	15·40	31·30	52·00	56·10	66·80	72·50

—*vide* Figs. 36 to 41. F. A. H. Schreinemakers gave 18·12 per cent. at 30°. A. Étard obtained the following values for S :

	1°	20°	61°	104°	150°	215°	312°	360°
S . .	4·1	10·4	30·2	48	60·8	76·9	91·8	97·4

but the results are considered to be too low. F. Flöttmann found the solubility at 15°, 20°, and 25° to be 0·321, 0·396, and 0·482 mols per litre, or 8·893, 10·822, and 12·980 per cent. R. Marc, M. le Blanc and W. Schmandt, and E. V. Murphree measured the rate of soln. of the salt in water, and showed that the process is determined by the rate of diffusion of the salt from the surface of the solid into the body of the liquid. J. Traube and W. von Behren discussed the formation of submicrons during the dissolution of the dichromate. T. Thomson said that an aq. soln. of the salt reddens litmus, and R. T. Thomson, and J. A. Wilson, that it is neutral towards lacmoid. The hydrolysis, $Cr_2O_7'' + H_2O \rightleftharpoons 2CrO_4'' + 2H^{\cdot}$, was studied by J. Sand and K. Kästle, and the equilibrium constant, $K = [CrO_4'']^2[H^{\cdot}]^2/[Cr_2O_7'']$, could not be determined satisfactorily owing to unrecognized disturbing conditions, but approximate estimates gave $K = 1{\cdot}5 \times 10^{-13}$ at 25° ; consequently, a $0{\cdot}1N$-soln. is 0·18 per cent. hydrolyzed. W. Herz and F. Hiebenthal gave for the solubility of potassium dichromate, S, one-sixth mol per litre, in n-normal soln. of lithium chloride, etc. :

LiCl	n . .	0	0·49	0·92	1·78	2·78	3·61	4·49
	S . .	2·89	2·78	2·55	2·26	1·85	1·37	1·32
NaCl	n . .	0·47	0·94	1·91	2·84	3·80	4·21	5·63
	S . .	2·91	2·98	2·79	2·62	2·33	2·24	2·06

where for LiCl, $S = 2{\cdot}90 - 0{\cdot}352n$; for NaCl, $S = 3{\cdot}195 - 0\text{-}230n$; for NH_4Cl, $S = 3{\cdot}066 - 0{\cdot}309n$; for $MgCl_2$, $S = 2{\cdot}95 - 0{\cdot}380n$; for $CaCl_2$, $S = 3{\cdot}02 - 0{\cdot}250n$; and for $SrCl_2$, $S = 3{\cdot}12 - 0{\cdot}210n$.

A. C. Robertson represented the catalytic action of the dichromate on hydrogen dioxide by the cyclic reactions : $K_2Cr_2O_7 + H_2O_2 = 2KCrO_4 + H_2O$, and $2KCrO_4 + H_2O_2 = K_2Cr_2O_7 + H_2O + O_2$. E. Pietsch and co-workers studied the surface-conditions in the reaction between potassium dichromate and hydrogen dioxide. For the action of hydrogen dioxide, *vide infra*, perchromates. J. W. Thomas found that potassium dichromate first forms potassium chloride, and chromium trioxide, and then a brown chromium oxide, but no chromyl chloride.

W. K. van Haagen and E. F. Smith found that hydrogen fluoride passed over heated potassium dichromate removes nearly all the chromium. According to F. Fichter and E. Brunner, if a dil. soln. of potassium dichromate is treated with fluorine, it becomes green and is reduced to a chromic salt, most probably the fluoride. Crude fluorine always containing free hydrogen fluoride; the action of fluorine upon an aq. soln. furnishes hydrofluoric acid and its conc. may be sufficient for the formation of chromic fluoride. In this case, fluorine acts as a reducing agent. This contradictory behaviour must be explained by the intermediate formation of hydrogen dioxide, thus: $2H_2O+F_2=H_2O_2+2HF$. The formation of hydrogen dioxide can be detected by working with a small quantity of chromic acid and in the presence of dil. sulphuric acid; under these conditions and by proper cooling we obtain the blue perchromic acid, soluble in ether. Perchromic acid is very unstable, losing oxygen and yielding chromic salts; in this manner the reduction of dichromate can be carried out quantitatively by prolonged treatment with fluorine. K. H. Butler and D. McIntosh observed that the dichromate is insoluble in liquid chlorine, and has no action on the b.p. of the liquid. According to E. M. Péligot, a soln. of potassium dichromate in boiling hydrochloric acid deposits, on cooling, potassium chlorochromate. R. E de Lury, and G. Kernot and F. Pietrofesa concluded from their observations on the action of potassium dichromate on acidic soln. of iodides that the reaction is of the first order with respect to the Cr_2O_7''-ion, nearly of the second order with respect to the $H^{\cdot}$-ion, and between the first and second order with respect to the I'-ion. R. F. Beard and N. W. Taylor showed that there are many anomalous results in connection with the reaction: $Cr_2O_7''+6I'+14H^{\cdot}=2Cr^{\cdots}+7H_2O+3I_2$, which disappear in the presence of $1{\cdot}5M$-NaCl. Two simultaneous reactions occur: $H^{\cdot}+I'+Cr_2O_7''\rightarrow HI.Cr_2O_7''$; and $2H^{\cdot}+2I'+Cr_2O_7''\rightarrow(HI)_2.Cr_2O_7''$. The velocity constant, k, is given by $k=14{\cdot}6[H^{\cdot}][I']+53000[H^{\cdot}]^2[I']^2$. The reaction was studied by N. A. Izgarischeff and A. K. Belaieff.

J. B. Senderens found that a soln. of potassium dichromate is decolorized by boiling it with sulphur, forming Cr_7O_{12}, or $3Cr_2O_3.CrO_3$, and a soln. of potassium sulphate and thiosulphate. A. Manuelli found that if a mixture of sulphur and the dichromate is heated in a sealed tube, chromic oxide is formed; and K. Brückner said that the reaction of the dichromate resembles that of the monochromate (*q.v.*) with sulphur—*vide supra*, the preparation of chromic oxide. A. A. Hayes said that hydrogen sulphide precipitates some hydrated chromic oxide mixed with sulphur; and P. Berthier, that sulphur dioxide colours the soln. green forming potassium chromic sulphate and dithionate. H. Bassett said that 94–95 per cent. of chromic sulphate and 5–6 per cent. of dithionate are formed. W. R. Hodgkinson and J. Young studied the action of dry sulphur dioxide on the salt. O. Popp represented the reaction with sodium thiosulphate: $2K_2Cr_2O_7+Na_2S_2O_3=K_2CrO_4+Cr_2O_3.CrO_3+K_2SO_4+Na_2SO_3$. W. H. Balmain found that when 3 parts of the dichromate are heated with 4 parts of sulphuric acid, chromium and potassium sulphates, water, and oxygen are formed, and he used this mode of preparing oxygen in preference to the potassium chlorate process—*vide supra*, chromium trioxide. G. Grather and T. Nagahama observed that potassium dichromate is reduced by sodium sulphide, sulphite, and thiosulphate in the order of increasing effect. M. Traube found that a mol of the salt dissolved in 3·5 parts of water and treated with 2 mols of H_2SO_4 in the cold is not decomposed, but it is decomposed by 3 mols of sulphuric acid with 0·5 part of water per mol of salt, but not with 2 parts of water. H. Schwarz made observations on this subject—*vide supra*, the preparation of chromium trioxide. E. C. Franklin and C. A. Kraus found that the salt is insoluble in liquid ammonia. The action of ammonium chloride has been indicated in connection with the preparation of chromic oxide. F. Santi found that a conc. soln. of ammonium chloride may convert the dichromate to chromic acid. According to G. B. Frankforter and co-workers, the reaction which takes place when the mixture is heated at 290° is different from that which occurs at a dull red-heat, the composition of the gas evolved and of the residue left after lixiviation being different in the two cases. A mixture of ammonium chloride and potassium dichromate does not undergo any change until a temp. of 210° is attained. The mixture then becomes yellowish-brown, owing to the formation of chromium dioxide. At 260°, a slate-coloured residue is obtained, which, on lixiviation with water, leaves small, greenish-black, iridescent spangles of a hydrated chromium oxide, $Cr_2O_3.2H_2O$. The change which takes place does not depend only on the temp., but also on the proportions of the salts employed. At 370°, in presence of a considerable excess of ammonium chloride, chromium chloride and ammonia are formed. If, however, the potassium dichromate is in large excess, a black residue is obtained, together with some unchanged dichromate. Under certain conditions, chlorine is liberated, and in some cases, a nitride of chromium is produced. It is supposed that the complexity of the reaction is largely due to the dissociation of ammonium chloride, which is the first change to take place when the mixture is heated. E. Mitscherlich, and F. Bothe found that a soln. of the salt in nitric acid deposits crystals of the terchromate. E. Kopp said that phosphorus reduces the soln. in sunlight or when heated, forming potassium chromate and a little chromium phosphate. A. Michaelis found that in a sealed tube, the salt is partially decomposed phosphorus trichloride at 166°, forming potassium chlorochromate, phosphoryl chloride, potassium phosphate, and chromium chromate. A mixture with carbon detonates slightly when heated. S. Levites studied the adsorption of the salt from aq. soln. by charcoal. E. J. Bowen and C. W. Bunn studied the photochemical oxidation of alcohols by dichromates. H. B. Weiser and E. B. Middleton attributed the conversion of potassium dichromate into chromate, observed by N. Ishizaka, to the disturbance of the equilibrium: $Cr_2O_7'' + H_2O \rightleftharpoons 2H^{\cdot} + 2CrO_4'$, by the preferential adsorption of $H^{\cdot}$-ions by the alumina. W. Kuczynsky found that a 4 per cent. soln. of potassium dichromate electrolytically pitted the surface of aluminium at 220 volts. J. Morland, and A. Reinecke studied the action of ammonium thiocyanate. B. Reinitzer found that the dichromate is insoluble in alcohol. E. J. Bowen and E. T. Yarnold studied the photochemical oxidation of ethyl alcohol by the dichromate. L. Godefroy studied the joint action of alcohol and chlorine or iodine; and A. Commaille, the joint action of acids and ether. F. W. O. de Coninck observed that 100 grms. of a sat. soln. in glycol contain 6 grms. of potassium dichromate. A. Naumann found that the salt is insoluble in benzonitrile, and acetone; and W. Eidmann, insoluble in acetone and methylal. D. Lindo observed that a brown colour is produced with phenol, and E. A. Parnell studied the joint action of phenol and hydrogen dioxide. J. Piccard and F. de Montmollin observed that the oxidation of aniline by potassium dichromate is a reaction of the second order. A. Commaille found that tannin gives a brown precipitate. For the action on gelatin, *vide supra*, chromic acid. G. Grather and T. Nagahama studied the reduction of dichromates to basic chromates by lactic acid, tartaric acid, glucose, dextrose, tannin, glycerol, formaldehyde, thiosulphates, sulphites, and sulphides, and found that the relative activity of these substances decreases in the order given. Methyl alcohol did not reduce the salt. J. W. Williams and E. M. Drissen investigated the action of the salt on cysteine. E. H. Riesenfeld and O. Hecht studied the photochemical reaction with ethylene glycol; and J. Plotnikoff, and D. S. Morton, the photoxidation of organic compounds by the dichromate.

S. Kern represented the reaction with magnesium: $K_2Cr_2O_7 + Mg + 2H_2O = MgCr_2O_7 + 2KOH + H_2$; and E. Heyn and O. Bauer observed that a dil. soln. of the dichromate dissolves iron, but soln. of certain concentrations retard the rusting of iron. W. P. Jorissen and G. M. A. Kayser discussed the reaction with sulphur and aluminium, and sulphur and iron. According to F. Margueritte, dil. soln. of potassium dichromate become paler in colour when treated with potassium chloride, nitrate, or sulphur, with ammonium nitrate or sulphate, or with sodium carbonate or tetraborate. H. J. P. Venn and V. Edge noted that basic cupric chlorides are formed by the action of a dil. soln. of potassium dichromate on cuprous chloride. When the dichromate is mixed with silicon and heated in the electric arc, L. Kahlenberg and W. J. Trautmann found that it is readily reduced to a porous green slag. J. C. Witt, and M. Neidle and J. C. Witt, studied the action of potassium dichromate on stannous sulphate and stannous chloride. According to E. R. Bullock, the reaction between silver in gelatin and a soln. containing potassium dichromate and a bromide, slightly acidified with acetic acid, only occurs in presence of potassium ferricyanide or copper sulphate, which appear to act as catalysts. The action of the catalyst is attributed to the greater simplicity of the initial ionic reaction: $\mathrm{Fe(CN)_6{}'''+Ag=Ag^{\cdot}+Fe(CN)_6{}''''}$, or $\mathrm{Ag+Cu^{\cdot\cdot}=Ag^{\cdot}+Cu^{\cdot}}$, as compared with $\mathrm{3Ag+Cr^{\cdot\cdot\cdot\cdot\cdot\cdot}=3Ag^{\cdot}+Cr^{\cdot\cdot\cdot}}$, which involves four ions instead of two. The concentrated soln. of potassium dichromate in $0\cdot3N$-NaOH increases up to 6·5 per cent. when shaken with animal charcoal—negative adsorption; with more dil. soln., the conc. is diminished—positive adsorption. The negative adsorption is explained on the assumption that the conc. of the water on the surface of the particles of charcoal is increased. E. Brentel recommended potassium dichromate as a standard for acidimetry. R. G. van Name and F. Fenwick studied the electrometric titration of ferrous salts with potassium dichromate; K. Someya, the action of potassium dichromate on potassium ferrocyanide; and M. M. Narkevich, the acceleration due to oxidation produced by the dichromate when copper dissolves in sulphuric acid.

W. K. Sullivan added that if an almost boiling soln. of a mol of potassium dichromate is treated with 2 mols of sulphuric acid, the orange-red crystals which separate on cooling appear to be *potassium dihydrosulphatodichromate* because they have the composition $\mathrm{K_2Cr_2O_7.2KHSO_4}$, but there is really nothing to show that this is a chemical individual. According to J. Fritzsche, *potassium disulphodichromate*, $\mathrm{K_2(Cr,S)_2O_7}$, or $\mathrm{KO.SO_2.O.CrO_2.OK}$, is formed in the preparation of chromic acid by the action of sulphuric acid on an excess of potassium dichromate. H. Reinsch, and H. Schiff, however, regarded the product so obtained as a mixture of potassium sulphate and dichromate. H. Schiff represented the action of fused potassium chlorochromate on potassium sulphate by the equation: $\mathrm{K_2SO_4+KCrO_3Cl=KCl+KO.CrO_2.O.SO_2.OK}$; and on potassium hydrosulphate, by: $\mathrm{KHSO_4+KCrO_3Cl=HCl+KO.CrO_2.O.SO_2.OK}$. He said that the colour of the salt is the same as that of potassium dichromate; and that it is decomposed by water into potassium sulphate and dichromate, and sulphuric acid.

L. Grandeau [5] prepared crystals of **rubidium dichromate**, $\mathrm{Rb_2Cr_2O_7}$, from a soln. of rubidium carbonate in an excess of a warm aq. soln. of chromic acid. F. A. H. Schreinemakers and A. Filippo's observations on the equilibrium conditions are summarized in Fig. 46. According to G. N. Wyrouboff, there are three forms, a monoclinic form and two triclinic forms, but observations by J. A. le Bel, W. Stortenbecker, and B. Gossner have established the existence of only two varieties—monoclinic and triclinic. W. Stortenbecker said that the monoclinic form is alone produced when soln. are crystallized below 35°, and the triclinic form when crystallization occurs at temp. above 75°; and J. A. le Bel said that the red triclinic variety alone crystallizes from acidic soln., whilst in the presence of a little alkali, the yellow monoclinic modification separates. The dimorphism is not conditioned by temp. alone. W. Stortenbecker added that the monoclinic and triclinic modifications of rubidium dichromate are monotropic, but that the small difference in stability between them retards the transformation of one into the other. If the time is great, the triclinic form is obtained, but a rapid crystallization gives sometimes the monoclinic, sometimes the triclinic, and sometimes a mixture of the two. This is probably the explanation of G. N. Wyrouboff's statement to the effect that, if crystals of one form are placed in contact with a sat. soln. of the other, they remain indefinitely without showing the slightest indication of transformation, no matter what the temp. G. N. Wyrouboff gave for the axial ratios of the monoclinic crystals $a:b:c=0\cdot596:1:0\cdot3388$, and $\beta=87°\ 8'$; while B. Gossner gave $1\cdot0202:1:1\cdot8081$, and $\beta=93°\ 28\cdot5'$. G. N. Wyrouboff found that the (010)-cleavage is incomplete, that the optic axial angle $2V=83°\ 16'$; the optical character is negative; and the sp. gr. is 3·021.

The axial ratios of the triclinic pinacoids are $a : b : c = 0{\cdot}5609 : 1 : 0{\cdot}5690$, and $\alpha = 91°\ 0'$, $\beta = 93°\ 52'$, and $\gamma = 81°\ 34'$. B. Gossner said that the (001)- and (010)-cleavages are complete, and that the (100)-cleavage is distinct. G. N. Wyrouboff found that the optical axial angle $2E = 107°\ 42'$; the optical character is positive; and the sp. gr. is 3·125. A. F. Hallimond discussed the mol. vols. of the isomorphous dichromates. The monoclinic form is considered by W. Stortenbecker to be the labile form more easily soluble in water; and he gave for the solubility, S per cent.:

		(14°)	18°	(26°)	30°	40°	(43°)	50°	65°
S	monoclinic	4·45	5·42	8·00	9·08	13·22	16·52	18·94	28·8
	triclinic	4·40	4·96	7·91	8·70	12·90	14·57	18·77	27·3

The data for the bracketed temp. were determined by G. N. Wyrouboff. According to J. A. le Bel, a red crystal placed in a soln. from which yellow crystals are separating passes into soln. so that the solubility of the two forms is not the same. F. A. H. Schreinemakers and A. Fillippo found that a sat. soln. contains 9·47 per cent. $Rb_2Cr_2O_7$ at 30°.

According to C. Chabrié,[6] the evaporation of an aq. soln. of 100 parts of cæsium chromate and 26 parts of chromium trioxide furnishes **cæsium dichromate,** $Cs_2Cr_2O_7$; F. R. Fraprie obtained the salt by treating cæsium chromate with sulphuric acid. The conditions of equilibrium worked out by F. A. H. Schreinemakers and D. J. Meijeringh are summarized in Fig. 47. C. Chabrié said that the pale red crystals are very stable; and F. R. Fraprie added that the crystals are triclinic with complete basal cleavage; and they are much more soluble in hot than in cold water. A. F. Hallimond discussed the mol. vols. of the isomorphous dichromates. F. A. H. Schreinemakers and D. J. Meijerinck represented for the solubilities of the different alkali dichromates, at 30°,

	Li	Na	NH_4	K	Rb	Cs
$M_2Cr_2O_7$	56·6	66·4	32·05	15·34	9·47	5·20

F. Dröge,[7] J. Schulze, and M. Gröger prepared **cupric dichromate,** $CuCr_2O_7.2H_2O$, by evaporating a soln. of cupric hydroxide in aq. chromic acid, and, if any green crystals separate, pouring off the clear soln., and evaporating the remaining liquor over conc. sulphuric acid. C. Freese obtained a basic chromate by this process. L. Balbiano obtained cupric dichromate by evaporating a soln. of the basic chromate in aq. chromic acid—if alcohol is added to the soln., a basic chromate is precipitated. A. Viefhaus obtained cupric dichromate from the soln. obtained by treating barium chromate with cupric sulphate, and J. Schulze, from the soln. of cupric carbonate in aq. chromic acid. F. Zambonini said that the triclinic crystals have the axial ratios $a : b : c = 0{\cdot}6133 : 1 : 0{\cdot}5117$, and $\alpha = 67°\ 2'\ 16''$, $\beta = 125°\ 14'\ 3''$, and $\gamma = 111°\ 26'\ 2''$; and the sp. gr. is 2·286 at 19°. F. Dröge, and J. Schulze said that the crystals of the dichromate are brownish-black; they lose all their water at 100°, and decompose at a red-heat; they deliquesce in air; are sparingly soluble in water without decomposition; they are also soluble in alcohol, and in aq. ammonia. N. Parravano and A. Pasta obtained cupric tetramminodichromate, $CuCr_2O_7.4NH_3.2H_2O$, in black prismatic crystals by evaporating an ammoniacal soln. of the compound which cupric dichromate forms with pyridine. J. Schulze said that if a soln. of cupric dichromate be treated with an excess of cupric carbonate, the basic product has a variable composition. A. and L. Lumière and A. Seyewetz observed that light reduces cupric dichromate gelatine less readily than gelatine with ammonium dichromate. N. Parravano and A. Pasta obtained complex salts with pyridine, aniline, and ethylenediamine. G. Krüss and O. Unger prepared **ammonium cupric dichromate,** $3(NH_4)_2Cr_2O_7.2CuCr_2O_7.6H_2O$, in dark brown tetragonal crystals, by evaporating or cooling a hot conc. soln. of 2 molar parts of ammonium dichromate and cupric dichromate. It loses its water, with some decomposition, at 100°; and at a higher temp., it decomposes with incandescence. The salt is soluble in water. A. Stanley reported **sodium copper dioxydichromate,**

$Na_2Cr_2O_7.2CuO.CuCr_2O_7.4H_2O$, by the action of a soln. of sodium dichromate on freshly-precipitated cupric hydroxide. The brown, microcrystalline powder loses water at 200°, and decomposes at a higher temp. It is almost insoluble in water; and only slightly soluble in alcohol.

According to H. Moser,[8] the action of chromic acid on a soln. of silver nitrate furnishes ruby-red crystals of **silver dichromate,** $Ag_2Cr_2O_7$; L. N. Vauquelin obtained the same salt from a soln. of silver chromate and nitric acid. O. Mayer, and W. Autenrieth used similar processes. R. Warington, C. Freese, W. Autenrieth, and E. Jäger and G. Krüss obtained the salt by adding potassium dichromate to a soln. of silver nitrate. A. Janek, and M. S. Dunin and F. M. Shemyakin studied the formation of rhythmic rings of silver dichromate. G. P. Baxter and R. H. Jess mixed potassium dichromate or chromic acid and silver nitrate in nitric acid, and crystallized silver dichromate from $0 \cdot 16N$- to $3N$-HNO_3, and dried the product at 150°, and afterwards powdered the product and dried it at 200° in a current of dry air. E. R. Riegel and M. C. Reinhard, D. A. Audalian, E. S. Hedges, and E. S. Hedges and R. V. Henley studied the formation of rhythmic rings of silver dichromate in gelatine—*vide supra*, silver chromate. R. Warington, and A. Helmsauer found that a silver plate becomes covered with scarlet crystals of silver dichromate when it is immersed in a soln. of potassium chromate and dichromate and sulphuric acid—a little chromic oxide is formed. G. H. Zeller said that heat hastens the formation of the crystals. The crystals appear dark brown or dark grey or black in reflected light, and scarlet-red or carmine-red in transmitted light. J. Schabus said that the triclinic pinacoids have the axial ratios $a:b:c=1 \cdot 5320:1:1 \cdot 0546$. H. G. F. Schröder found the sp. gr. to be 4·669; while G. P. Baxter and R. H. Jess gave 4·770 at 25°/4°. R. Warington found the dichromate to be sparingly soluble in water forming a bright yellow soln. which reddens litmus, and yields crystals on evaporation. When boiled with water, it forms dark green chromate, and an acidic soln. which deposits the dichromate on cooling; W. Autenrieth represented the reaction $Ag_2Cr_2O_7+H_2O=Ag_2CrO_4+H_2CrO_4$. O. Mayer gave for the solubility $1 \cdot 9 \times 10^{-4}$ mol per litre at 15°; and M. S. Sherrill and D. E. Russ, $7 \cdot 3 \times 10^{-3}$ mol per litre at 25°. M. S. Sherrill and D. E. Russ said that water, and nitric acid below $0 \cdot 06N$-HNO_3, decompose the dichromate with the separation of chromate. They found for the solubility, S milliatoms per litre, at 25°:

		HNO_3 .	$0N$-	$0 \cdot 01N$-	$0 \cdot 02N$-	$0 \cdot 04N$-	$0 \cdot 06N$-	$0 \cdot 08N$-	$0 \cdot 10N$-
S	Cr .	.	32·20	25·06	20·21	13·59	11·10	11·10	0·624
	Ag .	.	5·390	6·131	7·148	9·529	11·10	11·10	—
Solid phase.			$\underbrace{Ag_2CrO_4+Ag_2Cr_2O_7}$				$\underbrace{Ag_2Cr_2O_7}$		

R. Warington said that the salt is freely soluble in nitric acid and in aq. ammonia. A. Helmsauer said that when heated to redness, silver, and chromic oxide are formed. F. B. Hofmann observed that the powdered dichromate collects at the boundary surface when shaken with a mixture of water and benzene, toluene, xylene, or chloroform. S. H. C. Briggs observed the formation of complex salts with pyridine, $Ag_2Cr_2O_7.4$(and 6)C_5H_5N; and G. Krüss, and S. Darby, complex salts—$Ag_2Cr_2O_7.1$(and 2)$HgCy_2$. R. G. van Name and R. S. Bothworth found that when silver sulphate and dichromate, the former greatly in excess (99 : 1), are crystallized at a temp. of 25° from an acidic soln. (standard soln. of sulphuric acid), there are obtained solid soln. of sulphate and dichromate, ranging in colour from pale yellow to scarlet, and with the same rhombic form as the pure sulphate. These crystals contain up to 4·1 molar per cent. of dichromate. When a greater proportion of dichromate is present in the acidic soln., crystals of the dichromate alone separate. J. W. Retgers could not prepare solid soln. of these two salts. P. Ray and J. Dasgupta studied complexes with hexamethylenetetramine.

L. N. Vauquelin[9] prepared **calcium dichromate,** $CaCr_2O_7.3H_2O$, from a soln. of calcium oxide in chromic acid; and J. F. Bahr, from a soln. of calcium chromate in chromic acid, and evaporating the liquor over conc. sulphuric acid, or in vacuo. F. Mylius and J. von Wrochem supposed that the salt is tetrahydrated, but they obtained the dichromate, in red, six-sided plates, from a sat. soln. at 18°, when 61 per cent. of $CaCr_2O_7$ is present. When freshly prepared, the crystals of the trihydrate are red, but when left on a porous tile in a desiccator, they become yellowish-brown. They lose water when heated; and at a higher temp. they melt to a reddish-brown liquid. K. S. Nargund and H. E. Watson observed that calcium dichromate gives off oxygen at 250° in vacuo, and decomposes at 500° into calcium chromate and chromic oxide. Calcium dichromate behaves on heating like a mixture of calcium chromate and chromium trioxide. L. Schulerud could not prepare this salt. A. Naumann said that the dichromate is soluble in acetone. J. F. Bahr, A. Dalzell, and K. Preis and B. Rayman prepared **strontium dichromate,** $SrCr_2O_7.3H_2O$, from a soln. of strontium chromate in chromic acid. The crystals are coloured like those of potassium ferricyanide. G. N. Wyrouboff gave for the axial ratios of the monoclinic, prismatic crystals $a:b:c = 0{\cdot}6023:1:0{\cdot}5460$, and $\beta = 92°\ 32'$. The salt loses its water of crystallization at 110°; and at 220° all the water is expelled; and at a higher temp. oxygen is given off. K. Preis and B. Rayman, and W. Autenrieth obtained **barium dichromate,** $BaCr_2O_7$, by the action of a soln. of chromic acid on freshly precipitated barium chromate; and O. Mayer, by boiling barium chromate with chromic and nitric acids, and by adding barium chloride to a hot conc. soln. of chromic acid and washing the product with acetic acid. The brownish-yellow, or brownish-red, monoclinic prisms are decomposed by cold water into chromic acid and barium monochromate. O. Mayer said that the dichromate is not attacked by boiling acetic acid. According to J. F. Bahr, and E. Zettnow, the *dihydrate,* $BaCr_2O_7.2H_2O$, is formed by evaporating a soln. of barium chromate in chromic acid, but neither L. Schulerud nor W. Autenrieth could verify this. K. Preis and B. Rayman said that the dihydrate is produced by evaporating the mother-liquor from the preparation of the anhydrous salt. J. F. Bahr described the crystals as stellate groups of yellowish-brown needles; K. Preis and B. Rayman, as rhombic, brownish-yellow plates; and E. Zettnow, as dark yellow, doubly refracting scales which lose all their water at 120°. J. F. Bahr said that the salt is nearly all decomposed by water; and that barium dichromate separates from conc., aq. soln.; and barium monochromate from dil. aq. soln. For the equilibrium between barium chromate and dichromate, *vide* chromic acid.

B. Reinitzer[10] prepared **magnesium dichromate,** $MgCr_2O_7$; and he found the salt to be soluble in water; and slightly soluble in alcohol. G. A. Barbieri and F. Lanzoni obtained complex salts of magnesium dichromate with hexamethylenetetramine by the action of a conc. soln. of that base with potassium dichromate on a conc. soln. of magnesium acetate or sulphate. By evaporating in vacuo a soln. of a mol of zinc carbonate in 2 mols of cold chromic acid, J. Schulze[11] obtained dark reddish-brown crystals of **zinc dichromate,** $ZnCr_2O_7.3H_2O$. The crystals are hygroscopic in air; and freely soluble in water, but are decomposed by boiling water. The salt was also prepared by M. Gröger. C. O. Weber obtained what he regarded as *potassium zinc chromatodichromate,* $K_2Cr_2O_7.ZnCrO_4$. G. Krüss and O. Unger obtained a complex with mercuric cyanide; N. Parravano and A. Pasta, and S. H. C. Briggs, a complex with pyridine; and S. H. C. Briggs, a complex with aniline. J. Schulze obtained **cadmium dichromate,** $CdCr_2O_7.H_2O$, by the method employed for the zinc salt. The dark orange-brown crystals are easily soluble in water, and are not decomposed by that agent. G. Krüss and O. Unger, and M. Gröger also prepared this salt. N. Parravano and A. Pasta obtained complex salts with ethylenediamine, pyridine, and aniline. G. Krüss prepared hygroscopic **potassium cadmium dichromate,** $K_2Cr_2O_7.CdCr_2O_7.2H_2O$, which is soluble in water.

J. A. Atanasiu[12] found that in the electrometric titration of soln. of mercurous nitrate and potassium chromate the curve shows a break corresponding with

mercurous dichromate, $Hg_2Cr_2O_7$. A. J. Cox showed that **mercuric dichromate,** $HgCr_2O_7$, is also stable at 25°, with soln. having more than 10·46 mols of chromic acid per litre—Figs. 50 and 51—and this salt is the solid phase with soln. having between about 10·5 and 11·5 mols of chromic acid per litre. The same salt was prepared by A. Gawalowsky by the action of potassium dichromate on a soln. of mercuric nitrate. The deep carmine-red crystals were found by S. H. C. Briggs to form complex salts with pyridine. They also form complexes with other mercuric salts—chloride, cyanide, etc. K. A. Hofmann recommended a soln. of mercuric chromate in chromic acid for oxidizing carbon monoxide in gas-analysis. C. Hensgen prepared **ammonium oxydimercuriammonium dichromate,** $3(NH_4)_2Cr_2O_7[NH_2(HgOHg)]_2Cr_2O_7$, by boiling a soln. of ammonium dichromate with mercuric oxide; or by saturating a hot, conc. soln. of ammonium dichromate with yellow mercuric oxide, and washing with water, alcohol, and ether, the product which separates on cooling. The yellow needles or plates do not decompose in air. The salt decomposes with detonation when heated rapidly, and when slowly heated to 170°–200°, it forms a black, graphitic mass which detonates suddenly at a higher temp. It is insoluble in water, alcohol, and ether. Three-fourths of the nitrogen is evolved as ammonia when the salt is heated with potash-lye, and oxydimercuriammonium chromate is formed. The same product is obtained by treating the salt with aq. ammonia. The salt is freely soluble in hydrochloric acid, and sparingly soluble in dil. nitric or dil. sulphuric acid; and it is decomposed by warm, conc. acids.

G. Calcagni[13] prepared **aluminium oxydichromate,** $Al_2O(Cr_2O_7)_2$, as an amorphous paste by evaporating a soln. of precipitated aluminium hydroxide in chromic acid. R. E. Meyer obtained a soln. of **indium dichromate** by dissolving the oxide in a warm soln. of chromic acid; but on evaporation in a desiccator, he was unable to crystallize the resulting syrupy liquid. W. Crookes,[14] and M. Hebberling obtained **thallous dichromate,** $Tl_2Cr_2O_7$, by adding potassium dichromate to a soln. of a thallous salt. L. Schulerud emphasized the need for using an acidified soln. of the thallous salt, otherwise a mixture of thallous chromate and dichromate is precipitated. J. E. Willm obtained the dichromate by boiling the chromate with dil. sulphuric acid; and E. Carstanjen, by dissolving thallous carbonate in an excess of chromic acid. The orange-yellow or orange-red, crystalline powder is insoluble in water. F. J. Faktor found that thallous dichromate is somewhat soluble in water; and with a soln. of sodium thiosulphate, it forms yellow chromate, Tl_2CrO_4. If the soln. of the dichromate in sodium sulphate is warmed with ammonium chloride, hydrated chromic oxide is precipitated.

O. Mayer[15] obtained **lead dichromate,** $PbCr_2O_7$, by treating a soln. of lead acetate with chromic acid in the presence of conc. nitric acid, sp. gr. 1·4; K. Preis and B. Rayman, by treating lead chromate with a conc. soln. of chromic acid—cold or hot; and E. Hatschek, by the action of ammonium chromate on a soln. of lead nitrate. E. Hatschek also studied the formation of the dichromate by allowing the ammonium dichromate to diffuse into an agar-agar soln. of lead nitrate; and V. Moravek, by the diffusion of lead nitrate into gels. of potassium dichromate. A. J. Cox studied the conditions of its formation from lead oxide and chromic acid—*vide* Fig. 55. It is formed when a mol of lead oxide is shaken with a sat. soln. of 2·5 mols of chromic acid at 25°. The excess of chromic acid is washed out with a more dil. soln. of chromic acid, and the product dried by press. between porous tiles, and then in a desiccator over calcium chloride. K. Elbs and R. Nübling prepared the dichromate by electrolyzing a 130 per cent. soln. of chromic acid between lead electrodes with an anode density of 4 to 3 amps. per sq. dm. at 15°–20°. They also obtained evidence of the formation of *plumbic dichromate,* $Pb(Cr_2O_7)_2$. The preparation of lead dichromate was also studied by J. Milbauer, who found that the dichromate is precipitated from soln. which are seven times molar with respect to CrO_3. The crystals cannot be washed by water without hydrolysis, but they can be freed from chromic acid by washing with a

10 per cent. soln. of glacial acetic acid in acetone. Electrolytic processes were studied by W. Borchers, and C. Lückow. K. Preis and B. Rayman obtained a *dihydrate*, $PbCr_2O_7.2H_2O$, but this has not been confirmed. Lead dichromate appears as a reddish-brown powder, or in brick-red needles, or as a crystalline powder. It is decomposed by water into lead chromate and chromic acid; it is stable in a soln. with at least 6·87 mols of CrO_3 per litre at 25°. It is soluble in soda-lye.

As indicated in connection with the basic bismuth chromates, there is a possibility that *bismuth hydroxychromate*, $Bi(OH)(CrO_4)$, is **bismuthyl dichromate,** $(BiO)_2Cr_2O_7.H_2O$; and that *bismuthyl quaterchromate*, $Bi_2O_3.4CrO_3.H_2O$, is **bismuthyl hydroxydichromate,** $Bi(OH)(Cr_2O_7)$. A. J. Cox[16] did not find bismuth dichromate on the equilibrium diagram, Fig. 63. K. Preis and B. Rayman prepared **potassium bismuthyl dichromate,** $K_2Cr_2O_7.(BiO)_2Cr_2O_7$, by mixing soln. of 2 mols of bismuth nitrate, and 3 mols of potassium chromate, and allowing the precipitate to stand in contact with the mother-liquor to crystallize. The pale or dark orange-red, granular or scaly powder is decomposed by water. It is soluble in hydrochloric acid. If this salt be warmed with an excess of a conc. soln. of chromic acid, it forms a dark red, crystalline mass of **potassium bismuth hydroxydichromate,** $K_2Cr_2O_7.2Bi(OH)(Cr_2O_7)H_2O$. It is decomposed by water.

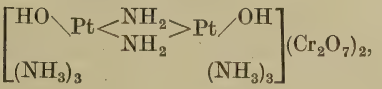
G. Calcagni[17] prepared a hygroscopic, amorphous paste of **chromium dichromate,** $Cr_2(Cr_2O_7)_3$, by evaporating a soln. of chromic oxide in chromic acid. P. Pfeiffer prepared **chromic trisethylenediaminodichromate,** $[Cr\ en_3]_2(Cr_2O_7)_3.2H_2O$, by the action of potassium dichromate on a soln. of the chloride. The yellow needles are slightly soluble in cold water. The salt is decomposed by heat or by exposure to sunlight. O. T. Christensen obtained **chromic nitritopentamminodichromate,** $[Cr(NH_3)_5NO_2]Cr_2O_7$, analogous to the chromate (*q.v.*). A. Werner and J. von Halban made **chromic thiocyanatopentamminodichromate,** $[Cr(NH_3)_5SCy]Cr_2O_7$, in an analogous manner. E. Wilke-Dörfurt and H. G. Mureck prepared **chromic hexantipyrinodichromate,** $[Cr(C_{10}H_{12}N_2)_6](Cr_2O_7)_3$. W. J. Sell, and E. Wilke-Dörfurt and K. Niederer prepared **chromic hexacarbamidodichromate,** $[Cr(CON_2H_4)_6]_2(Cr_2O_7)_3.3H_2O$, as well as **chromic hexacarbamidoperchloratodichromate,** $[Cr(CON_2H_4)_6](Cr_2O_7)ClO_4$; **chromic hexacarbamidodisulphatodichromate,** $[Cr(CON_2H_4)_6]_2(Cr_2O_7)(SO_4)_2.5H_2O$; **chromic hexacarbamidonitratodichromate,** $[Cr(CON_2H_4)_6](NO_3)(Cr_2O_7).H_2O$; **chromic chlorodichromate,** $[Cr(CON_2H_4)_6](Cr_2O_7)Cl.2H_2O$; and **chromic hexacarbamidobromodichromate,** $[Cr(ON_2H_4)_6](Cr_2O_7)Br.H_2O$. They also made **chromic hexacarbamidotetraborofluodichromate,** $[Cr(CON_2H_4)_6]_2(Cr_2O_7)(BF_4)_4$, but not $[Cr(CON_2H_4)_4](Cr_2O_7)BF_4$. G. Calcagni prepared **molybdenum dichromate,** $Mo(Cr_2O_7)_3$, as in the case of the chromium salt; but neither **tungsten dichromate,** nor **uranium dichromate** could be so prepared.

According to M. Gröger,[18] **manganese dichromate,** $MnCr_2O_7$, has not been prepared, but N. Parravano and A. Pasta obtained a complex salt with aniline; and with pyridine. S. H. C. Briggs also prepared a complex with pyridine. According to S. Husain and J. R. Partington, chromic acid acting on an excess of solid manganese carbonate yields a dark red soln. probably containing manganese dichromate. Only partly decomposed solid products could be obtained from this soln. Attempts to prepare double manganese dichromate and potassium chromate were not successful, because the latter is converted into dichromate with the precipitation of manganese dioxide. G. Calcagni prepared **ferric oxybisdichromate,** $Fe_2O(Cr_2O_7)_2$, or $(FeCr_2O_7)_2O$, from a soln. of ferric hydroxide in chromic acid. According to S. Husain and J. R. Partington, the prolonged action of a soln. of chromic acid on an excess of precipitated ferric hydroxide at 80° to 90°, yielded a soln., which, on evaporation at 90°, gave a residue with the composition of **ferric dichromate,** $Fe_2(Cr_2O_7)_3$, after it had been dried in vacuo. Ferric dichromate is a hygroscopic, brown solid which hydrolyzes when the aq. soln. is largely diluted. It decomposes a little at 100°, and at 140° the chromate radicle is decomposed, forming a black residue which slowly dissolves in boiling, conc. hydrochloric acid, forming a green soln. E. Wilke-Dörfurt and H. G. Mureck prepared ferric hexantipyrinodichromate, $[Fe(C_{10}H_{12}N_2)_6](Cr_2O_7)_3$.

J. Schulze[19] obtained a soln. of **cobalt dichromate,** by dissolving cobaltous oxide in a soln. of chromic acid. The liquid contained $CoO : CrO_3$ in the molar ratio 1 : 2. G. Krüss and O. Unger obtained **ammonium cobaltous dichromate,** $(NH_4)_2Cr_2O_7.CoCr_2O_7.2H_2O$, by evaporating in vacuo a hot conc. soln. of equimolar parts of ammonium dichromate and cobalt nitrate. The black, tabular crystals lose their water of crystallization at 105°. O. W. Gibbs prepared **cobaltic hexamminodichromate,** $[Co(NH_3)_6]_2(Cr_2O_7)_3.nH_2O$, in orange needles, by adding ammonium dichromate to a conc. soln. of the nitrate of the base. A. Werner and K. Dawe prepared **cobaltic bispropyldiaminodiamminodichromate,** $[Copn_2(NH_3)_2]_2(Cr_2O_7)_3.2H_2O$; and O. W. Gibbs, **cobaltic aquopentamminodichromate,** $[Co(NH_3)_5(H_2O)]_2(Cr_2O_7)_3.3H_2O$, by adding potassium dichromate to an aq. soln. of the nitrate. O. W. Gibbs also obtained **cobaltic nitritopentamminodichromate,** $[Co(NH_3)_5NO_2]Cr_2O_7$, by adding potassium dichromate to the corresponding nitrate ; the orange-yellow, crystalline precipitate may be crystallized from water acidified with acetic acid. S. M. Jörgensen obtained **cobaltic cisdinitritotetramminodichromate,** $[Co(NH_3)_4(NO_2)_2]_2Cr_2O_7$, as in the case of the corresponding monochromate ; so also with **cobaltic transdinitritotetramminodichromate,** prepared by O. W. Gibbs ; with **cobaltic nitratopentamminodichromate,** $[Co(NH_3)_5NO_3]Cr_2O_7.H_2O$, prepared by S. M. Jörgensen, and O. W. Gibbs ; with **cobaltic chloropentamminodichromate,** $[Co(NH_3)_5Cl]_2Cr_2O_7$, obtained by S. M. Jörgensen ; with **cobaltic iodopentamminodichromate,** $[Co(NH_3)_5I]_2Cr_2O_7$, prepared by A. Werner ; with **cobaltic dichlorotetramminodichromate,** $[Co(NH_3)_4Cl_2]_2Cr_2O_7$, prepared by A. Werner and A. R. Klein—G. Vortmann regarded the salt as *monohydrated ;* and with A. Werner and A. A. Wolberg's **cobaltic dibromotetramminodichromate,** $[Co(NH_3)_4Br_2]_2Cr_2O_7$. G. Vortmann prepared **cobaltic dioxydecamminodichromate,** $[CoO_2(NH_3)_{10}]_2(Cr_2O_7)_5.8H_2O$, from soln. of the chloride and potassium dichromate. P. Ray and P. V. Sarkar obtained **cobaltic chromatotetramminodichromate,** $[Co(NH_3)_4(CrO_4)]_2Cr_2O_7.H_2O$, by the action of chromic acid on the carbonatotetramminonitrate—it loses its water over sulphuric acid ; S. H. C. Briggs obtained the dihydrate by the action of potassium dichromate on a soln. of diaquotetramminonitrate. P. Ray and P. V. Sarkar found that **cobaltic dichromatotetramminodichromate,** $[Co(NH_3)_4(Cr_2O_7)]_2Cr_2O_7.H_2O$, is formed if a larger proportion of chromic acid be employed. P. Ray and P. V. Sarkar also prepared **cobaltic dichromatopentamminochromate,** $[Co(NH_3)_5(Cr_2O_7)]_2CrO_4.3H_2O$; from the corresponding carbonato-salts. S. H. C. Briggs prepared **cobaltic chromatoaquotriamminodichromate,** $[Co(NH_3)_3(H_2O)CrO_4]_2Cr_2O_7.2H_2O$, from soln. of cobalt trinitratotriammine and of sodium dichromate. P. Ray and P. V. Sarkar found that when cobaltic chromatopentamminochromate is recrystallized from dil. acetic acid, it furnishes **cobaltic aquopentamminochromatobisdichromate,** $[Co(NH_3)_5(H_2O)]_2(CrO_4)(Cr_2O_7)_2.H_2O$. S. H. C. Briggs added a cobaltic diaquotetrammino-salt to a large excess of sodium dichromate and obtained brownish-black crystals of **cobaltic enneamminodichromate,** $Co_2(Cr_2O_7)_3.9NH_3.4H_2O$.

S. H. C. Briggs[20] prepared **nickel dichromate,** $NiCr_2O_7.1\frac{1}{2}H_2O$, by boiling on an oil-bath 5·5 grms. of nickel carbonate (with 70 per cent. NiO), with a soln. of 10·5 grms. of chromium trioxide in 7·5 c.c. of water in a flask fitted with a reflux condenser. The crystalline powder has the colour of silver chromate. It deliquesces in air ; and is slowly dissolved by cold water, but rapidly by hot water. G. Chiavarino studied the ethylendiamine salt $NiCr_2O_7.3C_2H_4(NH_2)_2$.

G. B. Buckton[21] prepared **platinous tetramminodichromate,** $Pt[(NH_3)_4]Cr_2O_7$, by treating a soln. of the chloride with chromic acid, and the product drying in vacuo. When crystallized from hot soln. it resembles lead monochromate. It gives off water, ammonia, and nitrogen when heated, leaving platinum, and chromic oxide as a residue. It is sparingly soluble in water; insoluble in alcohol; and when boiled with alcohol and hydrochloric acid it forms aldehyde, chromic chloride, and platinic dichlorotetramminochloride. S. G. Hedin obtained **platinic sulphatotetrapyridinodichromate,** $[Pt(C_5H_5N)_4(SO_4)]Cr_2O_7$, by the method used for the corresponding chromate (*q.v.*). O. Carlgren and P. T. Cleve prepared **platinic dinitritotetramminodichromate,** $[Pt(NH_3)_4(NO_2)_2]Cr_2O_7$, by the action of hydrogen dioxide on the precipitate obtained by mixing soln. of platinous tetramminochloride and potassium dichromate. The lemon-yellow powder detonates when heated. P. T. Cleve prepared **platinic dinitratotetramminodichromate,** $[Pt(NH_3)_4(NO_3)_2]Cr_2O_7$ by the method used for the corresponding chromate; and likewise with **platinic dichlorotetramminodichromate,** $[Pt(NH_3)_4Cl_2]Cr_2O_7$. He also obtained **platinic hydroxyacetatotetramminodichromate,** $[Pt(NH_3)_4(HO)(CH_3COO)]Cr_2O_7.H_2O$, in orange-yellow, six-sided plates from the corresponding chloride and potassium dichromate. He also made **platinic hydroxysulphatotetramminodichromate,** $[Pt(NH_3)_4(OH)(SO_4)]_2Cr_2O_7$, in a similar way; likewise also with **platinic hydroxychlorotetramminodichromate,** $[Pt(NH_3)_4(OH)Cl]Cr_2O_7$. P. T. Cleve obtained **platinic dihydroxydiamidohexamminodichromate,**



$$\left[\begin{matrix} HO\diagdown Pt<{NH_2 \atop NH_2}>Pt\diagup OH \\ (NH_3)_3 \qquad\qquad (NH_3)_3 \end{matrix}\right](Cr_2O_7)_2,$$

as an orange-red precipitate from the corresponding nitrate and potassium dichromate.

§ 17. The Trichromates

M. Siewert[1] evaporated a soln. of ammonium dichromate in nitric acid, and obtained **ammonium trichromate,** $(NH_4)_2Cr_3O_{10}$. E. Jäger and G. Krüss recommended nitric acid of sp. gr. 1·39; but added that it is more convenient to prepare the salt from a soln. of ammonium dichromate in a conc. soln. of chromic acid. F. A. H. Schreinemakers studied the conditions of equilibrium, and his results are summarized in Fig. 29. The dark garnet-red, rhombic bipyramids were found by G. N. Wyrouboff to have the axial ratios $a:b:c=0{\cdot}8446:1:0{\cdot}8344$; the (100)-cleavage is distinct. The optic axial angle $2E=44°\ 30'$; and the optical character is positive. E. Jäger and G. Krüss gave 2·329 at 10°, and 2·342 at 13° for the sp. gr. M. Siewert said that the salt darkens at 110°–120°, and E. Jäger and G. Krüss said that the darkening which appears at 160°–170° is a sign of decomposition which begins at about 150°. Detonation occurs at about 190°. The residue is chromic oxide, or, according to M. Siewert, chromic oxide mixed with chromium trioxide. Water, nitrogen and nitrogen oxides—*e.g.* NO_2—are evolved. W. C. Ball said that the thermal decomposition resembles that with the dichromate (*q.v.*). The salt does not deliquesce, but it slowly decomposes in moist air forming chromic acid and ammonium dichromate; similarly also in contact with water.

F. A. H. Schreinemakers[2] did not find **lithium trichromate,** $Li_2Cr_3O_{10}$ in his study of the ternary system Li_2O–CrO_3–H_2O at 30°—Fig. 31. A. Stanley prepared dark red deliquescent crystals of **sodium trichromate,** $Na_2Cr_3O_{10}.H_2O$, by evaporating over sulphuric acid a soln. of sodium dichromate in chromic acid. The conditions of equilibrium, worked out by F. A. H. Schreinemakers, are summarized in Fig. 32. The crystals effloresce over sulphuric acid. The deliquescent crystals are soluble in water without decomposition even at 100°; and F. A. H. Schreinemakers found that at 30° a sat. soln. contains 70 per cent. $Na_2Cr_3O_{10}$. F. Mylius and R. Funk found that a soln. sat. at 18° contains 80·60 per cent. of salt and has a sp. gr. 2·059; and they gave for the percentage solubility at 0°, 15°, 55°, and 99°, respectively 80·03, 80·44, 82·68, and 85·78.

E. Mitscherlich[3] prepared **potassium trichromate,** $K_2Cr_3O_{10}$, from a soln. of potassium dichromate and nitric acid; F. Bothe recommended working with nitric acid of sp. gr. 1·210, and at 60°; E. Jäger and G. Krüss used nitric acid of sp. gr. 1·19. C. Schmidt used conc. nitric acid, but G. N. Wyrouboff said that if the nitric acid be too conc.—over 1·41 sp. gr.—some tetrachromate is formed. H. Reinsch, and C. J. B. Karsten observed the tendency of potassium nitrate to crystallize out with the trichromate in nitric acid soln.; and L. Darmstädter mistook the impure product for nitrochromate. M. Siewert separated the product from potassium nitrate by fractional crystallization. C. von Hauer, M. Siewert, and E. Jäger and G. Krüss obtained the trichromate by evaporating over sulphuric acid a soln. of potassium dichromate in chromic acid; F. A. H. Schreinemakers, and I. Koppel and E. Blumenthal studied the conditions of equilibrium, and the results are summarized in Figs. 36 to 41. Potassium trichromate furnishes deep red, prismatic crystals; and F. Bothe reported that the monoclinic prisms have the axial ratios $a:b:c=0{\cdot}8437:1:0{\cdot}8318$, and $\beta=101°\,0'$; the (010)-cleavage is distinct. F. Bothe gave 3·613 for the sp. gr.; H. G. F. Schröder, 2·676–2·702; L. Playfair and J. P. Joule, 2·655; and E. Jäger and G. Krüss, 2·667 at 10°—crystallized from chromic acid—and 2·648 at 11°—crystallized from nitric acid. The hardness is 2·5. I. Traube found the drop-weight of the molten trichromate to be 231 mgrms. F. Bothe said that the salt decrepitates a little when heated, and melts at 145°–150°; E. Jäger and G. Krüss said that the trichromate blackens at 220°, and melts at 250°. E. Groschuff said that the salt decomposes when melting. M. Berthelot gave for the heat of formation in the solid state: $(K_2CrO_4,2CrO_3)=14{\cdot}1$ Cals.; and T. Graham gave for the heat of soln., $-14{\cdot}2$ Cals. On exposure to air, the crystals lose their lustre and become opaque. The salt is freely soluble in water and there is a small fall in temp., and the trichromate decomposes into dichromate and chromic acid. P. Walden also inferred from the electrical conductivity, μ mho of the aq. soln. of a mol of the salt in v litres of water at 25°, *viz.*

v . .	32	64	128	256	512	1024
μ . .	275·9	282·9	286·1	286·4	283·4	278·2

that the salt is partially decomposed. L. A. Welo studied the magnetic susceptibility. F. Bothe found that the trichromate is soluble in alcohol, and the alcoholic soln. rapidly decomposes in light. A. Naumann found that the salt is soluble in acetone. G. N. Wyrouboff studied solid soln. of potassium and ammonium trichromates, and saw that the hexagonal crystals have the axial ratio $a:c=1:1{\cdot}0844$ with 58·5 to 69·7 per cent. of the ammonium salt.

F. A. H. Schreinemakers and H. Filippo[4] showed the conditions of equilibrium, Fig. 46, for **rubidium trichromate,** $Rb_2Cr_3O_{10}$, in soln. of chromic acid; and F. A. H. Schreinemakers and D. J. Meijeringh, the conditions of equilibrium, Fig. 47, of **cæsium trichromate,** $Cs_2Cr_3O_{10}$. The dark red, trigonal crystals were stated by F. R. Fraprie to have the axial ratio $a:c=1:1·5549$ and not to be isomorphous with the other trichromates.

M. Gröger[5] could not prepare **copper trichromate,** $CuCr_3O_{10}$. H. von Foullon passed carbon dioxide into a soln. of calcium chromate and obtained a precipitate corresponding with **calcium oxytrichromate,** $CaO.CaCr_3O_{10}$. K. Preis and B. Rayman prepared garnet-red deliquescent crystals of **strontium trichromate,** $SrCr_3O_{10}.3H_2O$, by the method employed in preparing the dichromate, but using a large excess of chromic acid. J. F. Bahr prepared **potassium barium trichromate,** $K_2Cr_3O_{10}.2BaCr_3O_{10}.3H_2O$, from a chromic acid soln. of barium and potassium dichromates. The reddish-brown needles are very deliquescent, and are decomposed by water.

M. Gröger[6] prepared dark red, deliquescent crystals of **zinc trichromate,** $ZnCr_3O_{10}.3H_2O$, by evaporating in vacuo a soln. of zinc dichromate in chromic acid. He also obtained **cadmium trichromate,** $CdCr_3O_{10}.H_2O$, in dark reddish-brown crystals by an analogous process. A. Gawalowsky obtained pale red crystals of *mercuric polychromate* by the action of an acidified soln. of potassium dichromate on mercury.

W. Crookes[7] obtained **thallous trichromate,** $Tl_2Cr_3O_{10}$, by digesting the chromate with sulphuric acid; and J. E. Willm, by digesting the dichromate with nitric acid. The red, crystalline powder behaves like the monochromate towards aq. and alcoholic hydrochloric acid. 100 grms. of water at 15° dissolve 0·0355 grm. of the trichromate, and at 100°, 0·2283 grm.

§ 18. The Tetrachromates

G. N. Wyrouboff[1] reported **ammonium tetrachromate,** $(NH_4)_2Cr_4O_{13}$, to be formed by crystallization from a soln. of ammonium dichromate in hot nitric acid of sp. gr. 1·41. E. Jäger and G. Krüss could not obtain the salt in this way, but they obtained it by slowly cooling a soln. of the trichromate in nitric acid of sp. gr. 1·39. F. A. H. Schreinemakers studied the conditions of equilibrium, and the results are summarized in Fig. 29. The brownish-red, crystalline aggregates are less stable than the lower chromates. E. Jäger and G. Krüss observed that the salt is hygroscopic, and is decomposed by moisture into the dichromate and chromic acid. The crystalline salt is stable in a dry atmosphere. It blackens when heated to 160°, melts at 170°, and decomposes suddenly at 175°, giving off nitric oxide, etc., and leaving a mixture of chromic oxide and chromium trioxide. J. J. Pohl reported crystals of *ammonium tetrachromate*, thought to be $(NH_4)_{10}Cr_4O_{17}$, in the preparation of the normal tetrachromate. J. Schabus found the monoclinic crystals had the axial ratios $a : b : c = 0·7458 : 1 : 0·4955$, and $\beta = 106° 51'$.

F. A. H. Schreinemakers could not prepare **lithium tetrachromate,** $Li_2Cr_4O_{13}$; but he showed that **sodium tetrachromate,** $Na_2Cr_4O_{13}.H_2O$, can exist under the conditions indicated in Fig. 34. F. Mylius and R. Funk prepared this salt by evaporating a soln. of sodium chromate in an excess of chromic acid. The garnet-red, deliquescent plates melt at 40°–50° with the separation of chromium trioxide. The salt dissolves in water without decomposition. A sat. soln. at 18° has 74·60 per cent. of $Na_2Cr_4O_{13}$, and has a sp. gr. of 1·926; and at 0°, 16°, and 22°, the respective percentage solubilities are 72·19, 74·19, and 76·01.

M. Siewert prepared potassium tetrachromate, $K_2Cr_4O_{13}$, by evaporating a soln. of potassium trichromate in conc. nitric acid slowly on a sand-bath, and cooling the mixture. The crystalline plates have the colour of mercuric iodide, and are freed from nitric acid by press. on porous titles, and by drying at 140°. E. Jäger and G. Krüss, and G. N. Wyrouboff used nitric acid of sp. gr. 1·4; and C. Schmidt, acid of sp. gr. 1·48–1·52. The contamination of the salt with nitrate led L. Darmstädter to regard it as a nitrochromate. E. Jäger and G. Krüss, and G. N. Wyrouboff obtained it by crystallization from a soln. of the trichromate in aq. chromic acid. F. A. H. Schreinemakers, and I. Koppel and E. Blumenthal studied the conditions of equilibrium, and the results are summarized in Figs. 36 to 41. H. Schwarz found that a soln. of a mol of potassium dichromate and 2 mols of sulphuric acid, first deposits crystals of the dichromate, and afterwards a mixture of potassium tetrachromate and sulphate. Potassium tetrachromate forms brownish-red or carmine-red, 8-sided plates and prisms, which are monoclinic; G. N. Wyrouboff gave for the axial ratios $a : b : c = 0·797 : 1 : 1·110$, and $\beta = 91° 42'$. The deliquescent crystals are stable in air; and E. Jäger and G. Krüss said that their sp. gr. is 2·649 at 11°; and that they melt at 215°; they are decomposed by water into trichromate and chromic acid.

F. Mylius and J. von Wrochem obtained dark red crystals of **calcium tetrachromate,** $CaCr_4O_{13}.6H_2O$, by evaporating over sulphuric acid a soln. of calcium carbonate in an excess of chromic acid. The salt is soluble in water.

C. F. Rammelsberg found that a soln. of chromic acid free from sulphuric acid, and half saturated with ammonia furnished a brownish-yellow salt—thought to be *ammonium hexachromate*. It decomposed with incandescence when heated. E. Jäger and G. Krüss could obtain only the dichromate by this process; and they were unable to isolate a more complex salt than the tetrachromate. This agrees with F. A. H. Schreinemaker's observations—Fig. 29.

§ 19. Perchromic Acid and the Perchromates

In 1847, L. C. A. Barreswil,[1] in his memoir : *Sur un nouveau composé oxygèné du chrome,* described how a deep blue soln. is produced when a conc. soln. of chromic acid is mixed with hydrogen dioxide. The soln. immediately begins to decompose with the evolution of oxygen, and this decomposition occurs more quickly with conc. soln. and with vigorous agitation. If sulphuric acid be mixed with potassium dichromate, and treated with hydrogen dioxide, oxygen is evolved and a soln. of chromic sulphate is formed. If ether be shaken up with the blue soln., the aq. layer is decolorized, and the ethereal liquor retains the blue product. The ethereal soln. is more stable than the aq. soln. If the ethereal soln. be evaporated, a conc. is attained at which the liquor suddenly decomposes with the evolution of oxygen and the formation of chromic acid. It is assumed that the blue soln. contained a perchromic acid CrO_{3+n} formed in accord with $2CrO_3+2nH_2O_2 \rightarrow 2CrO_{3+n}+2nH_2O$; and that the decomposition progresses $2CrO_{3+n} \rightarrow Cr_2O_3+(2n+3)O$, or $CrO_{3+n} \rightarrow CrO_3+nO$. F. H. Storer said that the blue coloration is so sensitive that it enables one part of potassium dichromate to be detected in 30,000 to 40,000 parts of water. G. Werther said that the presence of 0·0001 part of vanadate will mask the effect with 0·0001 part of chromate ; and C. Reichard noted that the disturbing effect of the molybdate and tungstate is not so great as that of the vanadate. C. Reichard observed that the presence of sodium hydrophosphate or hydroarsenate removes the injurious effect of vanadium.

W. M. Grosvenor found that the blue compound is also soluble in ethyl acetate or valerate, amyl chloride, amyl alcohol, and in amyl formate, acetate, butyrate, or valerate. The blue substance is not dissolved by carbon disulphide, benzene, light petroleum, toluene, nitrobenzene, aniline, paraffin and turpentine, carbon tetrachloride, chloroform, castor oil, bergamot oil, and oil of wintergreen. The soln. in ethyl acetate is said to be the most stable, but even that decomposes in about 23 hrs. G. Griggi said that the soln. in amyl alcohol is more stable than in ordinary ether, but W. M. Grosvenor did not agree. According to L. C. A. Barreswil, alkaloids—quinine, strychnine, etc.—in ethereal soln. form dirty violet precipitates insoluble in ether ; and when the precipitate is dried and treated with an acid, and ether, the blue soln. is again formed.

H. Aschoff found that the blue soln. is decolorized by ferrous salts; and, according to W. P. Jorissen and L. T. Reicher, by oxalic acid. With an excess of alkali-lye, L. C. A. Barreswil observed that oxygen is evolved and alkali chromate is formed. H. Aschoff found that lead oxide behaves like the alkali. C. F. Schönbein made some observations on the action of alkali on the blue soln. H. Aschoff found that if a dil. soln. of potassium hydroxide be added to the soln. until the ethereal layer is pale blue, water now colours the neutral aq. layer brownish-violet. The addition of more alkali results in the evolution of oxygen, and the formation of yellow alkali chromate. It is therefore inferred that the soln. of the free perchromic acid is blue, and that the salts are violet. In general, as shown by M. Martinon, acids decomposed the blue substance into salts of chromic oxide and oxygen, while alkalies form chromates.

M. Berthelot showed that with strong acids and a soln. of dichromate, hydrogen dioxide gives the blue colour of the hypothetical perchromic acid ; with the weaker acetic or phosphoric acid, the colour is violet not blue—due, it is suggested, to the formation of a brown substance along with the perchromic acid ; and with still weaker boric or hydrocyanic acid, the colour is brown and the rate of decomposition is slow. With a moderately conc. soln. of chromic acid, the liquid is first blue, then violet, brown, or even green ; but with dil. soln., at 10°, only traces of the blue perchromic acid are formed. The brown substance is the chief product. The action is most regular with an aq. soln. of a mol. of potassium dichromate per 16 litres, and an eq. quantity of a soln. containing a mol of hydrogen dioxide per 2 litres. The liquid first darkens in colour, rapidly becoming deep brown, and oxygen is liberated with effervescence, and during the reaction the liquid contains only traces of perchromic acid. The liquid then becomes clear and acquires its original colour—it contains neither hydrogen dioxide nor reduced chromic oxide. The same quantity of potassium dichromate will decompose an unlimited quantity of hydrogen dioxide. The brown intermediate product is probably a compound of hydrogen peroxide with chromic oxide: it decomposes rapidly, with regeneration of chromic acid, liberation of oxygen, and formation of water. As the thermal measurements show, the heat liberated by the reaction is identical with that liberated by the decomposition of hydrogen peroxide.

The brown colour of the unstable intermediate product points to the formation of chromium chromate. The hydrogen dioxide oxidizes the chromium chromate forming chromic acid and water. All this characterizes a catalytic reaction. Attempts by E. H. Riesenfeld, and E. Spitalsky to work out a detailed explanation of the catalyzed reaction have not been successful. When a large excess of hydrogen dioxide is present, the rate of decomposition is approximately proportional to the conc. of the chromic acid. If C_1 denotes the conc. in mols of K_2CrO_4 per litre, and k_1 the velocity constant,

C_1	0·001674	0·003132	0·02205	0·0313	0·05105	0·0674	0·1020
k_1 (obs.)	0	6·7	14·4	15·9	23·5	29·4	46·0
k_1 (calc.)	0·8	1·4	10·1	14·4	23·5	31·0	46·8

The reaction with dichromate is faster than with monochromate; and if C_2 denotes the conc. in mols of $K_2Cr_2O_7$ per litre, and k_2, the velocity constant of a first order reaction,

$C_2 \times 10^4$	0·3	1·2	2·4	4·8	7·83	9·6	45·4	90·8
k_2 (obs.)	4·5	17·2	33·7	65·3	100	123	394	829
k_2 (calc.)	4·1	16·4	32·0	65·8	108	123	394	829

The calculated values from $C_2 = 9{\cdot}6 \times 10^{-4}$ are no longer in accord with the observed. With dichromate alone, or in feebly acidic soln., some of the dichromate is reduced to a tervalent chromic salt; the proportion reduced depends on the acidity, *i.e.* on the H$^{\cdot}$-ion conc.; thus, with soln. containing 0·00546 mol Cr per litre at 25°, the percentage proportions of tervalent chromium are:

[H$^{\cdot}$]	0	0·00182	0·00354	0·00547	0·00783	0·00818	0·01089
Cr$^{\cdots}$	2·0	8·7	18·9	28·5	36·2	43·6	57·5 per cent.

These are equilibrium values in the sense that if a mixture contains more than this proportion of Cr$^{\cdots}$, oxidation to chromate occurs. E. Spitalsky found that when hydrogen dioxide is present in considerable excess, the rate at which it is decomposed is nearly independent of its conc., being approximately proportional to the cube root of the dioxide conc., but when the dioxide conc. has diminished to such an extent that the ratio $H_2O_2 : CrO_3$ is not more than 10 : 1, the velocity suddenly rises to two or three times its former value and then falls rapidly to zero, the dioxide being completely decomposed. The decomposition is relatively less rapid the greater the initial dioxide conc. for a definite conc. of chromic acid. When the dioxide is present in considerable excess, the rate of decomposition is approximately proportional to the chromic acid conc. The reaction velocity at any instant is completely determined by the dioxide and chromic acid conc. at that instant—for example, the sharp maximum in the velocity curve occurs at the same dioxide conc. for a definite chromic acid conc., independent of the initial conc. of the dioxide. E. H. Riesenfeld inferred that the H_3CrO_8-acid is first formed by the consumption of H$^{\cdot}$-ions; and as the acidity of the soln. is reduced, H_3CrO_7-acid appears. This is in harmony with E. Spitalsky's observation that a definite proportion of the chromic acid catalyst is reduced to a tervalent chromium salt. E. I. Orloff also discussed these complex reactions; and G. N. Ridley reviewed the general properties of perchromic acid.

H. Moissan said that the blue compound cannot be formed by the action of ozone, on a soln. of chromic acid, although A. Mailfert said that perchromic acid is formed if ether be also present. H. Moissan added that the blue perchromic acid is produced by the electrolysis of soln. of chromic acid only when hydrogen dioxide is first formed. E. H. Riesenfeld found that when a soln. of 16·6 grms. of chromic acid in 100 c.c. of a 30-per cent. soln. of sulphuric acid is electrolyzed, using platinum electrodes, and a porous cathode cell cooled by means of ether and carbon dioxide, a higher oxidation product of chromium, which can be detected by precipitation with ammonia, is probably formed, but decomposes as the conc. increases until the velocity of formation becomes equal to that of decomposition. Since chromic oxide, Cr_2O_3, and not chromic acid, is formed by the decomposition, the quantity of oxygen lost is greater than that produced by the electrolysis.

Two methods have been employed for finding the nature of the blue product: (i) By isolating the substance, its salts or their equivalent; and (ii) By determining the oxidizing power or the amount of oxygen set free during its decomposition. L. C. A. Barreswil found that when an acidified soln. of potassium dichromate is treated with hydrogen dioxide, 4 mols of oxygen are given off per mol of $K_2Cr_2O_7$; and he assumed that the perchromic acid, $Cr_2O_7.H_2O$, is formed as an intermediate compound. H. Aschoff represented the reaction: $2CrO_3+H_2O_2=H_2O+Cr_2O_7$ followed by $Cr_2O_7+4H_2O_2\rightarrow Cr_2O_3+4H_2O+4O_2$. B. C. Brodie found that with an excess of chromic acid, 6 gram-atoms of oxygen are evolved per 2 mols of CrO_3; and with an excess of hydrogen dioxide, 9 gram-atoms of oxygen; while T. Fairley's observations led him to assume that the intermediate perchromic acid is $CrO_6.3H_2O$. M. Martinon found that the maximum depth of blue coloration is developed when 2 mols. of CrO_3 and 4 mols. of H_2O_2 are present, and hence he regarded the perchromic acid as $4H_2O_2.2CrO_3$, *i.e.* H_4CrO_7, with the anhydride CrO_5. A. Carnot found that chromic acid is quantitatively reduced by hydrogen dioxide, and M. Berthelot observed that the amount of oxygen developed depends on whether the hydrogen dioxide is poured into the chromic acid or conversely. In the first case the result agrees with: $2CrO_3+3H_2O_2+3H_2SO_4=Cr_2(SO_4)_3+3O_2+6H_2O$, *i.e.* the chromic acid and hydrogen dioxide each lose the same quantity of oxygen. In the second case, the reaction seems to occur in two stages, $2CrO_3+H_2O_2=Cr_2O_7+H_2O$, and then $Cr_2O_7+4H_2O_2=Cr_2O_3+4H_2O+4O_2$ when 1·66 times as much oxygen is derived from the hydrogen dioxide as from the chromium trioxide. The intermediate Cr_2O_7 is considered to be the anhydride of the blue perchromic acid. E. Baumann confirmed M. Berthelot's conclusions; and observations were also made by A. Bach, and L. Marchlewsky. E. H. Riesenfeld represented the reaction between hydrogen dioxide and an excess of chromic acid by the equation: $2CrO_3+3H_2O_2=Cr_2O_3+3H_2O+3O_2$ with the intermediate formation of a Cr_2O_9-oxide: $2CrO_3+3H_2O_2=Cr_2O_9+3H_2O$ followed by $Cr_2O_9=Cr_2O_3+3O_2$; and with the hydrogen dioxide in excess, $2CrO_3+2H_2O_2=2CrO_4+2H_2O$ followed by $2CrO_4+5H_2O_2=Cr_2O_3+5H_2O+5O_2$, or else according to $2CrO_3+7H_2O_2=Cr_2O_{13}+7H_2O$ followed by $Cr_2O_{13}=Cr_2O_3+5O_2$. H. E. Patten argued that it is the hydrogen not the chromium which forms a higher peroxide. He said:

> When a sat. soln. of potassium dichromate is cooled to $-16°$ and treated with 2 per cent. soln. of hydrogen dioxide at the same temp., a white, solid substance separates and the soln. turns blue. If a cold sat. soln. of sodium acetate is added to this soln., it assumes the lake-colour of chromous acetate, and if left for half an hour the green colour of chromic acetate appears. Solid chromous acetate may be obtained by extracting the blue soln. with ether and adding sodium acetate to the blue ethereal soln. The electrical conductivity of the blue ethereal soln. of "chromous oxide" is less than 2×10^{-8} at 0°. The simplest explanation of these facts is said to be that chromic acid is reduced to the chromous state by hydrogen dioxide, and a higher oxide of hydrogen is produced.

This hypothesis, said K. A. Hofmann and H. Hiendlmaier, is untenable because much oxygen is evolved when hydrogen dioxide is mixed with chromic acid, and chromous salts are rapidly oxidized even by air, and they decompose water.

E. H. Riesenfeld pointed out that in the observations just indicated it is assumed that only one chemical individual is concerned in the reaction when either the hydrogen dioxide or the chromic acid is in excess. Actually, several products are probably produced, and these are all prone to decomposition. Hence, the term **perchromic acid** applied to the blue product does not necessarily refer to a chemical individual. H. Moissan tried to isolate the blue compound by evaporating the ethereal soln. at −20°; he obtained a deep indigo-blue, oily, liquid with a composition corresponding with $CrO_3.H_2O_2$. E. Péchard added baryta-water to a well-cooled soln. of chromic acid containing an excess of hydrogen dioxide and obtained a brown precipitate approximating $BaCrO_5$, but which O. Wiede regarded as a mixture of barium chromate and dioxide. C. Häussermann treated a mush of chromium hydroxide and water with sodium dioxide at 10°-20°, and obtained reddish-brown, efflorescent crystals, $Na_6Cr_2O_{15}.28H_2O$. The subsequent observations of O. Wiede, E. H. Riesenfeld and co-workers, and K. A. Hofmann and H. Hiendlmaier have shown that the following derivatives of the oxidation products of chromic acid can be recognized:

Compounds of the type: R_3CrO_8, or the red perchromates or **triperchromates.**—E. H. Riesenfeld and co-workers discovered that these compounds are formed when an alkaline soln. of chromic acid is treated with 30 per cent. hydrogen dioxide. For example, the ammonium salt, $(NH_4)_3.CrO_8$, is prepared as follows:

A mixture of 50 c.c. of 25 per cent. ammonia, 25 c.c. of 50 per cent. chromic acid, and 75 c.c. of water is cooled until ice begins to separate; 25 c.c. of 30 per cent. hydrogen dioxide is added, drop by drop, with constant shaking and keeping the temp. below 0°. The soln. becomes at first reddish-yellow, and then brownish-black, and in one or two hours, crystals of the ammonium salt separate out. These are washed with 95 per cent. alcohol until the runnings show no coloration due to chromic acid. The salt is dried with ether, or on a porous tile. The sodium and potassium salts can be obtained in an analogous manner.

The preparation of **ammonium triperchromate,** $(NH_4O.O)_3CrO_2$, or $(NH_4)_3CrO_8$, or *red ammonium perchromate,* has just been described. E. H. Riesenfeld and co-workers said that the salt forms reddish-brown, doubly refracting, octahedral crystals. The salt decomposes when heated to 40° forming ammonium chromate; and at 50° it explodes forming chromic oxide. It cannot be kept more than 2 days at ordinary temp. without losing oxygen. Percussion, or contact with sulphuric acid results in an explosion with the formation of chromic oxide dust. The salt forms a reddish-brown soln. with a little cold water, and, in the presence of a little alkali, it can be kept for a day without decomposition; when the soln. is boiled it forms oxygen and chromate, and this the more quickly, the smaller the conc. of the HO-ions. If the soln. be acidified, blue perchromic acid is formed, and this at once decomposes into oxygen and a chromic salt, without forming a chromate. The salt is insoluble in alcohol and ether, and is not attacked by the boiling liquids. Alcohol with more than 50 per cent. of water decomposes the salt at ordinary temp. with the formation of chromate and aldehyde, and in acidic soln. the chromate is reduced at the same time to a chromic salt. C. W. Balke showed that the salts are isomorphous with the corresponding pertantalates. The isomorphism between the pertantalates, percolumbates and perchromates was discussed by G. Böhm. E. H. Riesenfeld and co-workers prepared **sodium triperchromate,** Na_3CrO_8—possibly with H_2O—as previously indicated. The reddish-yellow plates are doubly refracting, and deliquescent. The salt cannot be satisfactorily dried; and it is preserved in an atm. sat. with water-vapour. It decomposes explosively at 115°. When dried, it loses oxygen and forms a yellow powder possibly NH_3HCrO_8. It is slightly soluble in cold water, and insoluble in alcohol and ether. E. H. Riesenfeld obtained in a similar manner **potassium triperchromate,** K_3CrO_8. The dark red prisms are doubly refracting and slightly pleochroic. The salt was kept for a month without decomposition; it does not decompose by percussion, and at 170°, it slowly gives off oxygen and forms the chromate. It decomposes explosively at 178°, or in contact with conc. sulphuric acid. The impure salt is explosive.

The salt is sparingly soluble in water, and insoluble in alcohol and ether. The f.p., and the electrical conductivity of the aq. soln. show that the salt is completely ionized.

(2) *Compounds of the type:* RH_2CrO_7 *or* $RCrO_5.H_2O_2$, *or the blue perchromates,* or **diperchromates.**—These compounds were discovered by O. Wiede. They are less stable than the red perchromates and are formed by the action of an alcoholic soln. of an alkali on the blue ethereal soln. of perchromic acid at —5° to —10°. K. A. Hofmann and H. Hiendlmaier obtained the compound by the action of, say, a soln. of ammonium chromate and nitrate on hydrogen dioxide; and E. H. Riesenfeld and co-workers, by the action of 30 per cent. hydrogen dioxide on an acidic soln. of a chromate—for example:

The ammonium salt, $(NH_4)H_2CrO_7$, is formed by mixing 100 c.c. of water, 5 c.c. of conc. hydrochloric acid, 10 grms. of ammonium chloride, 10 c.c. of 5 per cent. chromic acid, and 25 c.c. of 30 per cent. hydrogen dioxide. If in the preparation of the red perchromates, the mixture is treated with hydrochloric, oxalic or acetic acid, before the addition of hydrogen dioxide, the blue perchromates are formed.

O. Wiede, K. A. Hofmann and H. Hiendlmaier, and E. H. Riesenfeld and co-workers prepared **ammonium diperchromate,** $(HO.O)_2(NH_4O)CrO_2$, or $NH_4H_2CrO_7$, or *blue ammonium perchromate,* as just indicated. The bluish-black or violet crystals are pleochroic between pale reddish-brown and dark bluish-violet. If moisture be excluded, the salt can be kept some days without decomposition, but it gradually passes into ammonium dichromate. When rapidly heated, the salt burns with a hissing noise forming chromic oxide and nitrogen oxides. The salt dissolves in ice-cold water forming a violet-brown soln. which has a neutral reaction. The conc., aq. soln. rapidly decomposes with the evolution of oxygen, and the formation of ammonium dichromate; at a higher temp., the reaction proceeds more quickly still. Dil. sulphuric acid forms a blue soln. which quickly decomposes into oxygen and chromic sulphate. If a layer of ether be poured over the solid, or the ice-cold soln., and the liquid be acidified with sulphuric acid, the ether extracts the blue perchromic acid. The fixed alkalies act like water; with aq. ammonia, a gas is evolved and, with cold soln., the end-product is chromium triamminotetroxide. According to O. Wiede, the diperchromate is insoluble in alcohol, but according to E. H. Riesenfeld and co-workers, it is somewhat soluble in that menstruum. The salt is insoluble in ether, ligroin, and chloroform. Lead acetate, or barium chloride produces a violet-brown precipitate which soon gives off gas and forms the yellow chromate; silver nitrate gives a brownish-violet coloration which immediately forms reddish-brown silver chromate; ferric chloride gives a grass-green coloration which when heated, or allowed to stand, becomes yellow with the evolution of gas; with ferrous sulphate, gas is evolved and a yellow soln. is formed; copper sulphate is without action; and potassium permanganate forms a blood-red soln. which when acidified gives off oxygen, and deposits a manganese peroxide. O. Wiede, and E. H. Riesenfeld, prepared **potassium diperchromate,** KH_2CrO_7, in an analogous manner. The salt forms pleochroic prisms—red, and violet. The dark violet powder detonates a few degrees above 0°; the crystals are more stable, but they decompose at room temp. The salt dissolves in water, forming a brown soln. which, when warmed, gives off oxygen and forms potassium dichromate. Its reactions resemble those of the ammonium salt.

(3) *Compounds of the type:* $HCrO_5$ *with an organic nitrogen base,* or **monoperchromates.**—O. Wiede first prepared these compounds, which are blue or violet in colour, and assigned to them the formula $RCrO_3.H_2O_2$. E. H. Riesenfeld showed that they are to be regarded as complex salts of perchromic acid, $HCrO_5$, with an organic base—tetramethylammonium, $N(CH_3)_4CrO_5$, aniline, $HCrO_5.C_6H_5.NH_2$, pyridine, $HCrO_5.C_5H_5N$, piperidine, $HCrO_5.C_5H_{11}N$, or quinoline, $HCrO_5.C_9H_7N$. O. Wiede obtained them by the addition of the base to the blue ethereal soln. of perchromic acid cooled to 0°. E. H. Riesenfeld obtained the pyridine salt as follows:

A soln. of a gram of chromium trioxide in 100 c.c. of water is treated with 10 grms. of pyridine, and 25 c.c. of a 3 per cent. soln. of hydrogen dioxide at room temp. When the mixture is allowed to stand for a short time, blue crystals of $HCrO_5.C_5H_5N$ separate out.

O. Wiede prepared **tetramethylammonium monoperchromate,** $(CH_3)_4NCrO_5$, in violet, prismatic crystals, which form a brown soln. with water. It can be kept in the cold for some days. As previously indicated, complex salts were also prepared with aniline, pyridine, piperidine, and quinoline. The pyridine salt obtained by O. Wiede, K. A. Hofmann and H. Hiendlmaier, and E. H. Riesenfeld and co-workers furnished blue, rhombic plates, which were doubly refracting, and pleochroic. The salt is fairly stable when dry, but in moist air, it slowly decomposes forming chromic acid. It detonates with a small rise of temp., or by contact with sulphuric acid. Its general reactions are like those of the other perchromates.

(4) *Compounds of the type:* $CrO_4.3NH_3$, or **complex chromium tetroxides.**—These compounds were also discovered by O. Wiede, who also found that the 3 mols. of ammonia can be replaced by 3 mols of potassium cyanide indicating that the compound is chromium triamminotetroxide. E. H. Riesenfeld also prepared $2CrO_4.5KCy.5H_2O$, or $K_5[(CrO_4)_2(Cy)_5].5H_2O$; and K. A. Hofmann and H. Hiendlmaier, a compound with ethylene diamine, $CrO_4.C_2H_4N_2.2H_2O$, and one with hexamethylenetriamine, $CrO_4.C_6H_{12}N_4$. O. Wiede prepared the triamminotetroxide by shaking 100 c.c. of 10 per cent. hydrogen dioxide with a soln. of 10 grms. of chromium trioxide in 500 c.c. of water with 500 grms. of ether free from alcohol; and then adding 50 c.c. of cold, conc. ammonia. The precipitate which forms can be recrystallized from aq. ammonia. K. A. Hofmann and H. Hiendlmaier obtained it by the action of hydrogen dioxide on an ammoniacal soln. of ammonium dichromate; A. Wesch obtained the same product by treating ammonium chromate in a similar way; and A. Werner added hydrogen dioxide to a cold mixture of a soln. of chromic acid and pyridine; digested the precipitate in 25 per cent. aq. ammonia whereby the triammine was formed. E. H. Riesenfeld found that if red ammonium perchromate is treated with 10 per cent. aq. ammonia at 40°, the soln. furnishes acicular crystals and rhombic plates. These crystals are simply different habits of the same chemical individual, and do not represent two isomeric forms assumed to exist by K. A. Hofmann and H. Hiendlmaier. E. H. Riesenfeld recommended the following mode of preparation:

Add drop by drop 5 c.c. of 30 per cent. hydrogen dioxide to a mixture of 25 c.c. of 10 per cent. aq. ammonia and 5 c.c. of 50 per cent. chromic acid at 0°. When the liquid has been cooled by a freezing mixture for an hour, it is heated to 50° until the rapid evolution of gas has ceased, and the salt has nearly all dissolved. The filtered soln. is cooled to 0°, when brown needles of chromium triamminotetroxide separate out.

O. Wiede, K. A. Hofmann and H. Hiendlmaier, E. H. Riesenfeld and co-workers, A. Werner, and A. Wesch prepared **chromium triamminotetroxide,** $CrO_4.3NH_3$, as previously indicated. The salt appears in brown, doubly refracting prisms; when rapidly cooled, the hot soln. furnishes rectangular plates. O. Wiede reported the axial ratios of the rhombic, pyramidal crystals to be $a:b:c=1\cdot0076:1:1\cdot308$. K. A. Hofmann and H. Hiendlmaier said that there are α- and β-forms respectively with prismatic and tabular crystals; but E. H. Riesenfeld and co-workers showed that both forms have a sp. gr. 1·964 at 15°, and have identical physical properties; and concluded that they are really the same chemical individual. When heated the triamminotetroxide detonates and becomes incandescent forming chromic oxide. Y. Shibata measured the absorption spectrum. Strong acids liberate oxygen and form chromic salts; weak acids—*e.g.* acetic acid—do not change the crystals. E. H. Riesenfeld and co-workers added that the amount of oxygen developed depends on the conc. of the acid. Thus, with dil. acids, most of the oxygen is set free as a gas, and with conc. acids, fully half the oxygen remains in soln. as hydrogen dioxide. If the complex salt be dissolved in aq. ammonia, and then acidified, a transient blue coloration appears, oxygen is evolved, and a green chromic salt soln. is formed. When the complex salt is treated with fixed alkalies, oxygen and ammonia are evolved, and chromate is formed. The triamminotetroxide dissolves in aq. ammonia forming a brown soln., and likewise also in water, but with partial decomposition. The compound is insoluble in all other solvents tried. When 0·1 grm. is covered with alcohol-free ether, and a few drops of dil. sulphuric acid are added, and the mixture shaken, oxygen is evolved and the ether acquires a blue colour. When treated with potassium cyanide, the triamminotetroxide forms $CrO_4.3KCy$; with ethylenediamine, $CrO_4.C_2H_8N_2.2H_2O$; and with hexamethylenetetramine, $CrO_4.C_6H_{12}N_4$.

The four types of compounds are closely related chemically; and they can be transformed one into the other. Thus, if an aq. soln. of $(NH_4)_3CrO_8$ is treated with an acid, oxygen is evolved, and $(NH_4)H_2CrO_7$ is formed as a blue soln. and precipitate. If an excess of pyridine be added to either of these salts, $HCrO_5.C_5H_5N$ is formed; and when any of these three salts is treated with an excess of ammonia, the most stable of all the perchromates is produced, namely the triamminotetroxide, $CrO_4.3NH_3$. These changes can be all regarded as a result of the addition or abstraction of hydrogen dioxide. The formation of these compounds by the action of hydrogen dioxide on an aq. or ethereal soln. of chromic acid is taken by E. H. Riesenfeld to mean that the blue soln. does not contain one chemical individual—the $HCrO_5$ of O. Wiede—but rather must it be supposed that *der Grundstoff* is CrO_4 associated with hydrogen dioxide to form $2CrO_4.nH_2O_2$, where n is 1, 3, or 5. Thus, $2CrO_4+H_2O_2=2HCrO_5$; $2CrO_4+3H_2O_2=2H_3CrO_7$; and $2CrO_4+5H_2O_2=2H_2O+2H_3CrO_8$.

Other types have been reported. K. A. Hofmann and H. Hiendlmaier thought that the product obtained by the action of ammonium chromate on hydrogen dioxide in the presence of ammonia had the composition $(NH_4)_2CrO_6$ or $CrO_2(O.ONH_4)_2$, and that when treated with acetic acid it furnished blue $(NH_4)HCrO_6$ or $CrO_2(O.ONH_4)(O.OH)$; but E. H. Riesenfeld and co-workers showed that owing to defective analytical methods the compound with the assigned formula $(NH_4)_2CrO_6$ is identical with red R_3CrO_8; and that $(NH_4)HCrO_6$ is identical with O. Wiede's blue $(NH_4)H_2CrO_7$. H. G. Byers and E. E. Reid said that when the ethereal soln. of the blue perchromate is treated with potassium at −20°, hydrogen is evolved and the purplish-black precipitate produced has the composition **potassium perdichromate**, $KCrO_4$ or $K_2Cr_2O_8$. It is unstable, and rapidly decomposes with evolution of oxygen and the formation of potassium dichromate. By the addition of an alcoholic soln. of potassium cyanide to the blue soln., O. Wiede obtained a similar compound to which he ascribed the formula $KCrO_5.H_2O_2$. When the blue soln. is prepared without employing an excess of hydrogen dioxide, the compound obtained on the addition of potassium cyanide has the same composition as that produced by the action of potassium. The corresponding *sodium, ammonium, lithium, magnesium, calcium, barium, and zinc perdichromates* were prepared. It is inferred, therefore, that the blue ethereal soln. contains **perdichromic acid,** $H_2Cr_2O_8$. When the soln. is prepared in presence of an excess of hydrogen dioxide, it is probable that a more highly oxidized compound is also produced. These conclusions have not been confirmed.

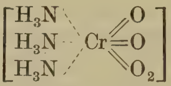
J. A. Raynolds and J. H. Reedy obtained a soln. of red perchromic acid by the action of 30 per cent. hydrogen dioxide on freshly-precipitated chromic hydroxide at 0°; and **calcium perchromate**, $Ca_3(CrO_6)_2.12H_2O$, by adding 30 per cent. hydrogen dioxide to a sat. soln. of calcium chromate at −5° to 0°, or by mixing soln. of calcium acetate and red perchromic acid. The dry salt is a buff powder which explodes at 100°, and when treated with acid, it furnishes blue perchromic acid.

The constitution of the perchromic acids has been investigated by E. H. Riesenfeld and co-workers. Cryoscopic measurements of the R_3CrO_8-salts are in agreement with the simple formula, but, owing to deviations through decomposition, and ionization, the results are equally in agreement with the doubled formula. In benzene soln., the $HCrO_5$-compounds also have a mol. wt. in agreement with the simple formula; and a similar remark applies to the $CrO_4.3NH_3$-compounds in aq. soln. Measurements of the electrochemical eq. of chromium in these soln. were unsatisfactory. It can be assumed that the perchromates contain peroxidic oxygen or the bivalent O_2-group, because, although hydrogen dioxide cannot be detected among the decomposition-products, an alkaline soln. of gold chloride, or potassium permanganate is reduced during the change. These reactions are characteristic of hydrogen dioxide.

It has not been proved whether the chromium in the perchromates is sexivalent or of a higher valency. The chromium in the tetroxide may be sexivalent with a bivalent (–O–O–)-group—*e.g.*:

$$\begin{matrix}O\\O\end{matrix}\!\gg Cr < \begin{matrix}O\\ \vdots \\O\end{matrix}$$

The triamminotetroxide can be formulated with the peroxidic oxygen occupying one position in the co-ordinate group:

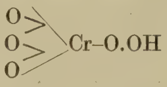


This explains how (i) the compound decomposes into hydrogen dioxide, etc., when treated with acids; (ii) the treatment with an aq. soln. of potassium cyanide furnishes $CrO_4.3KCy$; (iii) the formation of complex chromium ammines observed by E. H. Riesenfeld; and (iv) the treatment with hydrochloric acid in acetic acid soln. furnishes chromic dichloroaquotriamminochloride

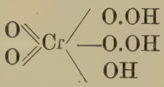
$$\left[\begin{matrix}Cl\\Cl\end{matrix}Cr\begin{matrix}H_2O\\(NH_3)_3\end{matrix}\right]Cl$$

It is not so easy to deal with the other perchromates. Excluding H. G. Byers and E. E. Reid's perdichromates, the perchromate analogue of permonosulphuric acid, H_2SO_5, and perdisulphuric acid, $H_2S_2O_8$, have not been prepared, and consequently the arguments valid with the persulphates cannot, by analogy, be applied to the perchromates. If the formulæ be doubled, the red and blue perchromates can be regarded as derivatives of sexivalent chromium: where $(H_3CrO_8)_2$ becomes $(HO.O)_3:CrO.O.O.CrO(O.OH)_3$, and $(HCrO_5)$ becomes $HO.O.CrO_2.O.O.CrO_2.O.OH$.

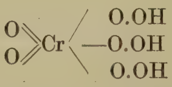
There is no serious objection to this mode of representing the composition of H_3CrO_8 perchromate, but mol. wt. determinations in the case of the $HCrO_5$-perchromate are against the doubled formula. Consequently the chromium probably has a valency higher than six. If nonivalent, $HCrO_5$ becomes $(O{=})_4Cr.O.OH$; H_3CrO_7 becomes $(O{=})_3Cr(OH)_2.O.OH$; and H_3CrO_8 becomes $(O{=})_3Cr(OH){=}(O.OH)_2$; and if septivalent,



Monoperchromic acid, $HCrO_5$.



Diperchromic acid, H_3CrO_7.



Triperchromic acid, H_3CrO_8.

The distinction between septivalent and nonivalent chromium turns on the number of peroxidic or —O.OH radicles. It is not possible to determine the number of peroxidic groups in acidic or alkaline soln. of the perchromate by means of potassium permanganate, because they decompose so rapidly. The red perchromates do not react with permanganate in strongly acid soln., but in alkaline soln. the amount of permanganate reduced increases with the alkalinity of the soln. to a maximum of 5·5 eq. Some peroxidic oxygen probably escapes without acting on the permanganate so that it is assumed that a mol. of the salt gives rise to 3 mols. of hydrogen dioxide. The escape of oxygen without reducing the permanganate is shown by the fact that no appreciable reduction occurs when the red perchromates are decomposed by strongly acidic soln. of permanganate, although oxygen is evolved; and by the fact that the blue perchromates are similarly decomposed in acidic or alkaline soln. of permanganate but only a trace of reduction occurs. This means that there are three peroxidic groups in H_3CrO_8; and this favours the hypothesis that *in the blue perchromates the chromium* is septivalent. This makes the H_3CrO_8-acid, **triperchromic acid,** $(HO.O)_3CrO_2$; the H_3CrO_7-acid, **diperchromic acid,** $(HO.O)_2(HO)CrO_2$; and the $HCrO_5$-acid, **monoperchromic acid,** $(HO.O)CrO_3$. A. R. y Miro found that triperchromic acid, H_3CrO_8, instead of consuming 5 mols of oxygen per mol of dichromate in the reaction $2CrO_8''+12H^{\cdot}=2Cr^{\cdot\cdot\cdot}+6H_2O+5O_2$ actually furnishes 4·6 to 6·5. This is explained by assuming the formation of an acid analogous to $HCrO_5$. Septivalent chromium is not in harmony with the position of chromium in the periodic table ; and it makes chromium an exception to the other elements forming per-acids. If $HO.O.Cr(=O)_3$ be the hydrogen dioxide derivative of a chromic acid, $HO.Cr(=O)_3$, the acid is analogous with permanganic acid, $HO.Mn(=O)_3$. This analogy is supported by the isomorphism between the chromates and manganates ; and between the chromium and manganese alums.

§ 20. Chromium Fluorides

C. Poulenc[1] prepared **chromium difluoride,** or **chromous fluoride,** CrF_2, by the action of hydrogen fluoride on red-hot chromium ; and by the action of hydrogen fluoride on chromous chloride at ordinary temp. A. Mourlot obtained it by the action of hydrogen fluoride on chromous sulphide. G. Herrmann did not obtain good yields in the electrolytic reduction of chromic fluoride soln. K. Jellinek and A. Rudat found that the difluoride is produced by heating the trifluoride in hydrogen : $2CrF_3+H_2\rightleftharpoons 2CrF_2+2HF$. According to C. Poulenc, chromous fluoride forms a grey mass which consists of monoclinic crystals of sp. gr. 4·11. The salt is reduced by hydrogen at a red-heat. K. Jellinek and A. Rudat found that in the reaction $CrF_2+H_2\rightleftharpoons Cr+2HF$, at the absolute temp. 873°, 973°, and 1073°, the values of log (p^2_{HF}/p_{H_2}) are respectively $-3·70$, $-3·02$, and $-2·56$; those of log $(p_{HF}/p_{H_2}p_{F_2})$, 33·12, 29·83, and 27·15 ; and log p_{F_2}, $-36·82$, $-32·85$, and $-29·50$, where p_{F_2} is the vap. press. of the difluoride. The heat of formation is 152 Cals. C. Poulenc observed that the difluoride is transformed into chromic oxide when heated in air. It is sparingly soluble in water. Boiling hydrochloric acid dissolves the salt; and at a red-heat, hydrogen sulphide forms chromous sulphide. The salt is but slightly attacked by hot sulphuric acid, or dil. nitric acid; it is insoluble in alcohol; and forms chromic oxide and finally chromate when fused with alkali carbonates.

W. Traube and co-workers prepared **ammonium chromous fluoride,** $NH_4CrF_3.2H_2O$, from soln. of chromous acetate and ammonium hydrofluoride dissolved in very little water. The soln. gradually deposits a pale blue powder which is fairly stable in dry air, and forms a pale blue soln. with water. Dil. nitric acid oxidizes it with the evolution of nitrogen oxides. They also prepared **potassium chromous fluoride,** $KCrF_3$, in an analogous manner.

If dry chromic oxide, not previously calcined, be treated with an excess of hydrofluoric acid, and the soln. evaporated to dryness and strongly heated, **chromium trifluoride,** or **chromic fluoride,** CrF_3, is formed. H. St. C. Deville obtained it by passing hydrogen fluoride over a mixture of fluorspar and chromic oxide heated to redness in a carbon tube; and C. Poulenc said that by heating anhydrous chromic chloride, hydrated chromic fluoride or amorphous chromic fluoride, to 1200° in a current of hydrogen fluoride, when crystals of anhydrous chromic fluoride are formed. The dark green, needle-like crystals were found by C. Poulenc to have a sp. gr. of 3·78, and to melt over 1000°. H. St. C. Deville said that the salt melts at a high temp., and volatilizes only a little at the m.p. of steel; it sublimes at the highest temp. of the gas-blowpipe, forming regular octahedra. C. Poulenc found that the salt sublimes at 1100°–1200°. A. Speransky found that the lowering of the f.p. in conc. aq. soln. corresponds with the existence of both simple molecules, CrF_3, and doubled molecules, Cr_2F_6. E. Petersen gave for the heat of formation in aq. soln., $Cr_2O_3+6HF_{aq.}=2CrF_{3aq.}+3H_2O+50{\cdot}3$ Cals. H. von Wartenberg gave $(Cr,\frac{3}{2}F_{2aq.})=171{\cdot}3$ Cals. for the anhydrous trifluoride. G. Magnanini studied the absorption spectrum; and A. Speransky found that the electrical conductivity of aq. soln. shows that only a small proportion of the salt is ionized. The soln. of the violet modification conducts electricity three times better than that of the green. G. Gore electrolyzed a conc. soln. of chromic fluoride acidified with hydrofluoric and hydrochloric acids, and found that the liquid became hot; no gas was liberated at the cathode, but chlorine and ozone were liberated at the platinum anode which was not corroded. C. Poulenc showed that the salt is reduced by hydrogen at dull redness. The heat of formation is 230·95 Cals. per mol—*vide infra,* the dichloride. Steam transforms chromic fluoride into chromic oxide. Chromic fluoride is insoluble in water, and alcohol; hydrogen chloride transforms it into chromic chloride; hot hydrochloric, sulphuric, and nitric acids attack chromic fluoride only a little; hydrogen sulphide converts it into black sulphide; and molten alkali nitrate or carbonate converts it into chromate. A. Costachescu prepared complex pyridine salts.

According to J. J. Berzelius, brown chromic chromate forms a rose-coloured soln. when treated with hydrofluoric acid; and the soln. dries to a rose-coloured salt which dissolves in water and gives a brown precipitate with ammonia. E. Petersen observed that if chromium, or hydrated chromic oxide be dissolved in hydrofluoric acid, and the soln. evaporated, there remains a green, crystalline mass, soluble in water. G. Herrmann studied the electrolytic reduction of soln. of chromic fluoride. A. Werner and W. Costachescu obtained the insoluble green *trihydrate,* $CrF_3.3H_2O$, or $[Cr(H_2O)_6]CrF_6$, by heating the hexahydrate with water on a water-bath. That part which becomes insoluble is the trihydrate. It is also formed by heating the hemiheptahydrate to 105°. C. Poulenc obtained the *hemiheptahydrate,* $CrF_3.3\frac{1}{2}H_2O$, by pouring an aq. soln. of the fluoride into hot alcohol. The salt is a green crystalline powder which can be obtained in small prisms by allowing the soln. to diffuse slowly into one another. It is soluble in water. A. Werner and W. Costachescu obtained another form of the hemiheptahydrate by double decomposition between the hexahydrated chloride and ammonium chromium hexafluoride. The pale green, crystalline powder loses a mol. of water at 105°. This salt is represented by the formula $[Cr(H_2O)_6]CrF_3].H_2O$, and it is considered to be isomeric with the tetrahydrate, which is regarded as the monohydrated **chromic triaquotrifluoride,** $[F_3\equiv Cr\equiv(H_2O)_3]H_2O$, whose aq. soln. has an acid reaction, and does not give the reactions of fluorides. The electrical conductivities of a mol of the salt in 100, 500, and 1000 litres of water are, respectively, 22, 26·6, and 31·0. A. Loesche's analysis corresponds with $Cr_3F_8.11H_2O_4$, or $CrF_2.Cr_2F_6.11H_2O$. A. Hiendlmayr prepared **chromic aquopentamminotrifluoride,** $[Cr(NH_3)_5(H_2O)]F_3$, by the action of hydrofluoric acid on the corresponding hydroxide. If the yellow compound be allowed to stand in contact with its mother-liquor, it furnishes **chromic fluopentamminodifluoride,** $[Cr(NH_3)_5F]F_2$, as a flesh-coloured precipitate which dries to a carmine-red powder. R. Köpp obtained what he regarded as a *tetrahydrate*, from a soln. of hydrated chromic oxide in hydrofluoric acid, and he recommended it for use as a mordant. It was probably imperfectly dried hemiheptahydrate. A. Werner and W. Costachescu treated a soln. of 20 grms. of violet chromic nitrate in the smallest possible quantity of water, with a conc. soln. of 8·69 grms. of potassium fluoride, and washed the crystalline mass of violet *hexahydrate*, $CrF_3.6H_2O$, or **chromic hexaquofluoride,** $[Cr(H_2O)_6]F_3$. The salt was dried first by press. between bibulous paper, and afterwards in a desiccator for 3–4 days over conc. sulphuric acid. The salt loses 3 mols. of water at 60°–70° in 8 hrs., and more at a higher temp., and it then decomposes. The salt is sparingly soluble in water, and is hydrolyzed in aq. soln. The electrical conductivity, μ mhos, of a mol of the salt in v litres at 18°, is μ=152·1 for v=100; μ=196·5 for v=500; and μ=223 for v=1000—about half that of the violet chloride. The conductivity does not change with time. When treated with sulphuric acid, it forms chromic hexaquosulphate. When the moist crystals are kept, they pass into the *enneahydrate*, $CrF_3.9H_2O$, or $[Cr(H_2O)_6]F_3.3H_2O$. The conversion occurs spontaneously when the crystals are washed, or pressed slightly with a spatula. G. Fabris prepared the enneahydrate, by treating a soln. of violet chromic sulphate with ammonium fluoride—not in excess. When the salt is heated, water is evolved, and the residue is green. The violet crystals are sparingly soluble in water; and insoluble in alcohol, and in a soln. of ammonium fluoride; the soln. in hydrochloric acid is violet; that in potash-lye is green. F. Hein and co-workers, and R. Weinland and W. Hübner, studied some complexes with organic compounds. F. Pintus prepared the complex with pyridine, chromic tripyridinofluoride, $[CrPy_3F_3]$; and E. Wilke-Dörfurt and H. G. Mureck, **chromic hexantipyrinoborofluoride,** $[Cr(COC_{10}H_{12}N_2)_6](BF_4)_3$.

J. J. Berzelius prepared ammonium, potassium, and sodium chromium fluorides as green sparingly soluble powders, but he did not give an analysis. R. Wagner found that **ammonium chromium pentafluoride,** $(NH_4)_2CrF_5.H_2O$, is formed when ammonia is passed into an aq. soln. of chromic fluoride, and the product extracted with absolute alcohol. Emerald-green, octahedral crystals are formed by treating the product with hydrofluoric acid. A. Werner and A. Gubser represent this salt as *ammonium aquopentafluoride*, $[Cr(H_2O)F_5](NH_4)_2$. R. Wagner, A. Werner and W. Costachescu, and E. Petersen obtained **ammonium chromium hexafluoride,** $3NH_4Cl.CrF_3$, by mixing soln. of chromic and ammonium fluorides; H. von Helmolt, by the action of a hot soln. of ammonium fluoride on freshly precipitated chromic oxide; and G. Fabris, by warming violet chromic sulphate with an excess of ammonium fluoride. The green, octahedral crystals are freely soluble in water, and sparingly soluble in a soln. of ammonium fluoride. A. Werner and A. Gubser represent this salt by the formula $[CrF_6](NH_4)_3$. R. F. Weinland and co-workers prepared the guanidine salt, $[CrF_6]H_3.3CH_5N_3$. R. Wagner prepared **sodium chromium pentafluoride,** $2NaF.CrF_3.\frac{1}{2}H_2O$, as a green, sparingly soluble powder, from a mixed soln. of sodium and chromic fluorides. A. Moberg observed that a soln. of chromic fluoride gives a green precipitate when treated with potassium fluoride. O. T. Christensen, and R. Wagner prepared **potassium chromium**

pentafluoride, $2KF.CrF_3.H_2O$, in green crystals, insoluble in water, and soluble in conc. hydrochloric acid. O. T. Christensen, and C. Poulenc also prepared **potassium chromium hexafluoride,** K_3CrF_6, from a mixed soln. of chromic fluoride and potassium hydrofluoride, or by melting a mixture of these two salts, and extracting the mass with hydrofluoric acid. A. Duboin obtained crystals of the salt by adding chromic oxide or fluoride to molten potassium hydrofluoride. The green crystals of the complex salt have a sp. gr. 2·93 at 0°. The green crystals are insoluble in water, and are not decomposed by a boiling soln. of sodium carbonate. A. Duboin said that the crystals are freely soluble in nitric and hydrochloric acids. G. O. Higley prepared **copper chromium pentafluoride,** $CuCrF_5.5H_2O$, by evaporating a soln. of eq. molar proportions of copper and chromium fluorides in hydrofluoric acid; and recrystallization from hydrofluoric acid. The salt loses water at 200°. He also obtained **zinc chromium pentafluoride,** $ZnCrF_5.7H_2O$, in an analogous manner. F. Ephraim and P. Barteczko prepared **thallous chromium enneafluoride,** $3TlF.2CrF_3$, by evaporating a mixed soln. of chromic and thallous fluorides. It forms a green, crystalline powder.

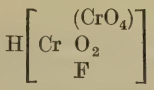
§ 21. Chromium Oxyfluorides

O. Unverdorben [1] prepared what was thought to be a higher chromium fluoride by distilling in a platinum or lead retort a mixture of equal parts of lead chromate and fluorspar and 3 parts of fuming sulphuric acid. H. Rose employed potassium dichromate instead of lead chromate. It was discovered by V. Oliveri, in 1886, that the product is not chromic fluoride at all, but rather **chromium dioxydifluoride,** CrO_2F_2. The bivalent CrO_2-radicle is sometimes called the chromyl-radicle, so that the compound is also named **chromyl fluoride.** W. P. Evans used O. Unverdorben's process; and C. L. Jackson and G. T. Hartshorn, and V. Oliveri, H. Rose's process. O. Ruff heated antimony pentafluoride and chromyl chloride and obtained a yellow gas thought to be chromyl fluoride. The red vapour of chromyl fluoride, said O. Unverdorben, produces severe oppression of the lungs; and J. B. A. Dumas found that when cooled, the vapour condenses to a red liquid. O. Unverdorben observed that the vapour is decomposed by water with the evolution of heat forming chromic and hydrofluoric acids; and when exposed to air, it forms a yellow cloud, and deposits crystals of chromium trioxide. Chromyl fluoride combines with ammonia; it converts arsenic trioxide into arsenic trifluoride and chromium trioxide; boric oxide forms boron trifluoride and chromium trioxide; and silica and even glass form silicon tetrafluoride and chromium trioxide. Organic substances are destroyed by the vapour; alcohol and ether form chromium trifluoride; and F. Wöhler said that when the vapour is passed into absolute alcohol a brownish-green powder is deposited and heat is evolved. C. L. Jackson and G. T. Hartshorn found that benzoic acid is converted into difluobenzoic acid; and V. Oliveri, that toluene reacts as in the case of chromyl chloride, forming a black mass, which, with water, gives benzaldehyde. O. Unverdorben found that mercury slowly decomposes the vapour of chromyl fluoride; and W. P. Evans found that zinc or sodium reduces the vapour to chromium (*q.v.*).

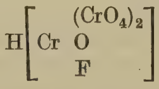
L. Varenne treated a nitric acid soln. of ammonium trichromate with hydrofluoric acid, and obtained red, efflorescent crystals of **ammonium dichromyl tetrafluochromate,** $(NH_4)_2CrO_4.2CrO_2F_2$. The crystals attack glass; and they are decomposed by acids, forming hydrofluoric and chromic acids. If ammonium dichromate be used instead of the trichromate, L. Varenne obtained **ammonium chromyl difluochromate,** $(NH_4)_2CrO_4.CrO_2F_2$, which can be regarded as **ammonium fluochromate,** NH_4CrO_3F, the salt of a hypothetical *fluochromic acid*, $HCrO_3.F$. The red crystals change slowly when exposed to air; they attack glass; and are decomposed by heat. A. Werner [2] represented the salt by $NH_4[CrO_3F]$. A. Streng boiled potassium dichromate with conc. hydrofluoric acid, and on cooling the clear soln., obtained ruby-red crystals of **potassium fluochromate,** $KCrO_3F$. L. Varenne obtained the salt by a similar process; and A. Ditte, by cooling a hot soln. of potassium fluoride and chromic acid in eq. proportions. A. Streng, and L. Varenne said that the crystals become reddish-yellow and melt when exposed to air; they cannot be preserved in glass vessels; they melt when heated, forming a dark brown liquid, and at a red-heat lose 11 per cent. in weight; at a still higher temp. in glass vessels, oxygen is evolved and silicon tetrafluoride is formed. A. C. Oudemans said that the salt decomposes as in the analogous case of the chlorochromates. A. Streng, and L. Varenne found that the salt is soluble in water, and boiling water converts the salt into potassium dichromate and hydrofluoric acid. The salt can be recrystallized from a little water; with sulphuric acid it forms hydrofluoric and chromic acids; and with alkalies, potassium fluoride and chromate are formed. F. Olsson prepared **potassium dioxydifluochromate,** $KF.CrO_2F.H_2O$, as a yellowish-brown precipitate by adding an aq. soln. of $4CrO_3.Cr_2O_3$ to an excess of a soln. of potassium fluoride in 40 per cent. hydrofluoric acid at 0°. This is thought to be a complex containing quinquevalent chromium.

R. Weinland and H. Staelin prepared a series of fluochromates which are represented on the co-ordination theory by the formulæ $H[CrO_3F]$ in the simplest case, analogous to $H_2[CrO_4]$ for the chromates. The fluochromates are represented by pyridine, quinoline, guanidine and **tetramethylammonium fluochromate,** $[CrO_3F]N(CH_3)_4$; and by **silver fluochromate,** $Ag[CrO_3F]$, obtained as a dark red, sparingly soluble powder by mixing a soln. of chromic acid with hydrofluoric acid, and silver acetate. They prepared **thallous fluochromate,** $Tl[CrO_3F]$, in an analogous way as a brownish-yellow powder sparingly soluble in water. Comparing the formula, $H[CrO_3F]$, with those for the polychromic acids—*vide supra*—there follow:



$$H\left[Cr\begin{matrix}(CrO_4)\\O_2\\F\end{matrix}\right]$$

Fluodichromates.



$$H\left[Cr\begin{matrix}(CrO_4)_2\\O\\F\end{matrix}\right]$$

Fluotrichromates.

The **fluodichromates** are represented by ethylenediamine fluodichromate,

$H[Cr(CrO_4)(O_2)F].en$; and the **fluotrichromates** by pyridine and quinoline fluotrichromates. A. Hiendlmayr[3] prepared **chromic fluopentamminochromate,** $[Cr(NH_3)_5F]CrO_4$, from a conc. soln. of the fluoride and potassium chromate. R. Weinland and co-workers prepared complex salts of the fluoride with pyridine, *o*-toluidine, guanidine, and aniline.

§ 22. Chromium Chlorides

F. Hein and co-workers,[1] and F. Pintus obtained evidence of the formation of a transient **chromium monochloride,** CrCl, in their study of the action of magnesium phenyl bromide on chromic chloride: $4Mg(C_6H_5)Br+3CrCl_3=Cr(C_6H_5)_4Cl+2MgBr_2+2MgCl_2+2CrCl_2$; followed by $4CrCl_2+4Mg(C_6H_5)Br=Cr(C_6H_5)_4Cl+3CrCl+2MgCl_2+2MgBr_2$—the initial evolution of hydrogen as attributed to the action of the monochloride.

A. Moberg prepared **chromium dichloride,** or **chromous chloride,** $CrCl_2$, by passing dry hydrogen over heated violet chromic chloride as long as hydrogen chloride is given off. If the temp. be too high, A. Moberg, W. Gregory, and J. J. Berzelius found that chromium is produced. The hydrogen must be freed from traces of oxygen: to do this, A. Moberg passed the hydrogen over heated spongy platinum, while E. M. Péligot scrubbed the gas with a soln. of stannous chloride in potash-lye. E. M. Péligot observed that it may be formed at the same time as the trichloride when dry chlorine is passed over a red-hot mixture of chromic oxide and charcoal. C. E. Ufer, H. Moissan, and I. Koppel obtained chromous chloride by passing hydrogen chloride over chromium at a high temp. T. Döring showed that the reaction, $2CrCl_3+H_2=2HCl+2CrCl_2$, is irreversible. H. Moissan also obtained chromous chloride by heating chromic chloride in the vapour of ammonium chloride; and A. Recoura, by dehydrating the hydrates at 250° in a current of nitrogen—W. A. Knight and E. M. Rich worked at 180° in vacuo. F. Wöhler observed that an aq. soln. of chromous chloride is formed by dissolving chromium in hydrochloric acid; H. Löwel, H. Moissan, and A. Recoura, by reducing a soln. of chromic chloride with zinc; and K. Someya, by reducing soln. of chromic salts with zinc- or lead-amalgam. G. Herrmann studied the electro-reduction of soln. of chromic chloride to chromous chloride and obtained the following yields at 50°–60°:

Current density	. .	1	2	3	4	5 amps.
Efficiency	Pt electrode .	16	35	67	50	25 per cent.
	Pb electrode .	95	81	65	45	25 ,,

W. Traube and co-workers prepared conc. soln. of chromous chloride by the prolonged electrolytic reduction of aq. soln. of green chromic chloride, using lead plates as electrodes and employing a current desnity of 0·175 amp. per sq. dm. The electrolysis of chromous chloride soln., using an iron cathode, results in the formation of a cathodic deposit of metallic chromium mixed with chromium oxides.

W. Traube and A. Goodson protected the soln. from air during electrolysis by covering them with light petroleum ; they found that the most favourable conditions for the economic reduction are the electrolysis of the violet chromic salts in moderately acid conc. soln., using a lead cathode, and a current density of about 2·5 amp. per sq. dm. The more common green salts, in aq. soln., require a greater expenditure of current than the violet salts, but they yield much more conc. soln. and are, therefore, more suitable in the end for the production, at any rate, of soln. rich in chromous salts but not entirely free from chromic salts. The same slower reduction of the green complexes is observed when soln. are treated with zinc. M. C. Taylor and co-workers found that in a two-compartment cell with a spiral, spongy lead cathode, and five graphite anodes, a soln. of chromic chloride is reduced to chromous chloride. With a total cathode surface of 1·24 sq. dm. and a current of 1·6 amps. a current efficiency of 96 per cent. may be obtained over the period required to reduce 87 per cent. of the chromium if the soln. is rapidly stirred and if the current is reduced when hydrogen commences to be evolved. With an unchanged current the efficiency is only 53 per cent. for the same amount of reduction. F. Hein and co-workers found that phenyl magnesium bromide reacts with chromic chloride, forming chromous chloride, $3CrCl_3+4C_6H_5MgBr=(C_6H_5)_4CrCl+2MgBr_2+2MgCl_2+2CrCl_2$; and that the reduction proceeds further, forming **chromium monochloride,** CrCl, thus, $4CrCl_2+4C_6H_5MgBr=(C_6H_5)_4CrCl+3CrCl+2MgCl_2+2MgBr_2$. H. Moissan said that if the aq. soln. be evaporated, it deposits crystals of the *hexahydrate ;* but A. Recoura, and W. A. Knight and E. M. Rich observed that it is the *tetrahydrate* that is formed under these conditions—*vide infra.*

Analyses of the anhydrous salt were made by A. Moberg, H. Moissan, E. M. Péligot, and A. Recoura. K. Someya discussed the colour of chromous salt soln. Chromous chloride may furnish white pseudomorphs after chromic chloride ; it may form white needles ; or colourless radiating masses. F. W. Clarke and J. P. Grabfield gave 2·751 for the sp. gr. at 14°/4° ; and W. Biltz and E. Birk, 2·878 at 25°/4°. For the mol. vol., *vide infra,* hydrated chromic chloride. A. Moberg said that the salt is readily melted. L. F. Nilson and O. Pettersson found the vap. density (air unity) to be 7·80 between 1300° and 1400° ; 7·27 between 1400° and 1500° ; and 6·22 between 1500° and 1600°. The theoretical value for $CrCl_2$ is 4·256. The decrease which occurs with a rise of temp. indicates that the dissociation of more complex molecules is approaching completion. A. Recoura gave for the heat of hydration : $CrCl_{2solid} \rightarrow CrCl_2.4H_2O_{cryst.}+16{\cdot}6$ Cals. ; and for the heat of soln., 18·6 Cals. K. Jellinek and R. Koop found for the reaction $Cr+Cl_2=CrCl_2$, 76·68 Cals. F. Allison and E. J. Murphy studied the magneto-optic properties. W. Hampe found that molten chromous chloride is an electrical conductor, and on electrolysis, chromium separates at the negative pole. H. Küssner found that a chromium anode in soln. of potassium chloride dissolves with different valencies between 2 and 6. At low temp. and small current densities, the valency approaches 6, but at higher temp. no conditions could be found which gave only one kind of ion. Similar results were obtained with alcoholic soln. of zinc chloride. S. Meyer gave 47×10^{-6} mass units for the magnetic susceptibility ; and R. H. Weber gave for the atomic magnetism 0·0182. B. Cabrera and S. P. de Rubies studied this subject. G. Breit and H. K. Onnes found that the order of the magnetic susceptibility is unchanged when the frequency of alternation of the magnetic field is increased to 369,000, for the value in the alternating field is 0·75 of the value for the direct field.

The reaction $CrCl_2+H_2=2HCl+Cr$ was studied by K. Jellinek and R. Koop. The anhydrous salt is stable in dry air, but it deliquesces in moist air and becomes green owing to oxidation. The autoxidation of soln. of chromous chloride in the absence of air with the development of hydrogen was studied by A. Moberg, H. Moissan, and A. Recoura. M. Berthelot observed that the change is accelerated by acids ; and T. Döring, that it is accelerated by precipitated gold ; and W. Traube and co-workers, that it is accelerated by palladium salts. A. Asmanoff showed that the reaction is accelerated by platinum in the presence of hydrochloric acid; and with sulphuric acid the reaction is slower. The unimolecular reaction with 0·1N-HCl at 29·4° has a velocity constant of 0·0129; and with 0·1N-H_2SO_4, 0·0115. Without platinum the evolution of hydrogen with 10N- sulphuric acid cannot be detected, but it can be observed with hydrochloric acid. Ammonium chloride in N-HCl gives a measurable yield of hydrogen even when platinum is absent. The reaction proceeds more rapidly in ammoniacal soln., and is fastest in soln. containing ammonium sulphate. The speed of the reaction increases as the conc. of the ammonia increases. The reaction in ammoniacal soln. is accelerated by chromic salts. W. Traube and W. Lange found that the conversion of chromous to chromic salts is accelerated by a metal of the platinum group, or by a hydrogen acceptor, as well as by substances which cannot be regarded as hydrogen acceptors. The reaction is interpreted according to the scheme $Cr(OH)_2 \rightarrow Cr(:O).OH+H$. The reaction was studied by H. Wieland and F. G. Fischer. E. S. Hedges and J. E. Myers showed that the evolution of hydrogen in the autoxidation of chromous chloride in the presence of platinum may be periodic, chromous chloride dissolved in *water* with the evolution of much heat forming a blue soln. which rapidly turns green owing to the absorption of oxygen, and, according to E. M. Péligot, the formation of Cr_2OCl_2—a reaction which A. Recoura found to be attended by the evolution of 100·8 Cals. Soln. of chromous chloride were used by F. O. von der Pfordten, R. P. Anderson and J. Riffe, W. Manchot and J. Herzog, for the absorption of *oxygen* in gas analysis—*vide* **8**. 49, 1. A. Mailfert studied the action of ozone. Chromous chloride is transformed into chromic chloride by *chlorine*, and A. Recoura gave for the heat of the reaction $(CrCl_{2solid}, Cl_{gas})$=39·4 Cals.; $(CrCl_{2soln.}, Cl_{gas}) = CrCl_{3green\ soln.}+51{\cdot}4$ Cals.; and $(CrCl_{soln.}, Cl_{gas})=CrCl_{3violet\ soln.}+60{\cdot}8$ Cals. G. S. Forbes and H. W. Richter dissolved chromous chloride in ice-cold 0·1N-HCl in an atm. of hydrogen or carbon dioxide free from all traces of oxygen. The mercury or platinum potential rose continuously to a maximum value which became constant after two days. If traces of oxygen are present, the potential fluctuated irregularly. When referred to the hydrogen electrode as zero, at 25°, $E=-0{\cdot}400+0{\cdot}065 \log (Cr'''/Cr'')$. The maximum potential with platinum was about 0·16 volt lower than with mercury, and hydrogen was evolved. G. Herrmann studied the electrolytic reduction of soln. of chromic chloride. If *hydrogen chloride* is passed for a long time into a conc. soln. of chromic chloride, cooled to 0°, a bluish powder of *chromous hydrochloride*, $3CrCl_2.2HCl.13H_2O$, is formed; it is stable at 0°, but decomposes at 20°. A. Moberg, and E. M. Péligot found that the blue aq. soln. gives a pale green precipitate with *potassium fluoride*, but no precipitate with *potassium bromide, or iodide*. V. Rothmund, and R. Stahn studied the reduction of *perchlorates* by chromous salts. E. M. Péligot obtained a black precipitate with *potassium sulphide*—it is insoluble in an excess of the alkali sulphide. *Potassium sulphite* gives a brick-red precipitate. A. Moberg said that *ammonia* gives a pale blue precipitate and a little hydrogen is evolved—the supernatant blue soln. becomes red in air—but E. M. Péligot said that no hydrogen is given off; and added that a mixture of ammonia and ammonium chloride gives a blue soln. which becomes red on exposure to air. W. Peters found that chromous chloride absorbs ammonia, forming ash-grey **chromous hexamminodichloride,** $CrCl_2.6NH_3$, and when this is kept in vacuo it forms a violet **chromous triamminodichloride,** $CrCl_2.3NH_3$. W. Biltz and E. Birk found that the sp. gr. of the hexamminodichloride is 1·392 at 25°/4°. F. Ephraim and S. Millmann discussed the stability of these salts; and W. Biltz and E. Birk, the mol. vols. K. Kraut described the formation of some chromous ammines—*vide infra*. W. Traube and W. Passarge prepared lilac-coloured **chromous dihydrazinochloride,** $CrCl_2.2N_2H_4$, by precipitation on adding a soln. of hydrazine hydrate to a soln. of the chloride. The precipitate is washed with water, alcohol, and ether, and dried over sulphuric acid. R. Stahn studied the reduction of *potassium azide* by chromous salts. W. Traube and W. Passarge found that chromous salts reduce *nitrous* oxide in the presence of alkali hydroxide to nitrogen; *nitric acid*, and *hydroxylamine* are reduced quantitatively to ammonia, but the reduction of *nitrous acid* to ammonia is not quantitative. For the action of *nitric oxide*, studied by G. Chesneau, J. Sand and O. Burger, and V. Kohlschütter, *vide* **8**. 49, 35. A. Moberg found that *sodium hydrophosphate* gives a blue precipitate; and sodium carbonate gives a yellowish-green precipitate and the supernatant liquor becomes yellow. W. Traube and W. Passarge showed that soln. of chromous salts are gradually oxidized, especially in acidic soln., with the liberation of hydrogen: $2CrO+H_2O=Cr_2O_3+H_2$; in consequence, they are able in the presence of water to reduce compounds with double or triple linkages. Thus, they reduce *acetylene* to ethylene, but not *ethylene* to ethene; maleic and fumaric acids are reduced to succinic acid in acidic and alkaline soln.; *cinnamic and phenylpropionic acids* yield β-phenyl propionic acid with an alkaline suspension of chromous oxide; and *benzaldoxime* is transformed into benzylamine. E. M. Péligot found that *potassium thiocyanate* gives no precipitate. R. Stahn studied the reduction of *thiocyanic acid*, and of *potassium cyanide*. R. Ripan discussed the hydrolysis of chromic salts by potassium cyanate. J. J. Berzelius found that potassium cyanide gives a white precipitate insoluble in excess; E. M. Péligot found that *potassium ferrocyanide* gives a yellowish-green precipitate; and *sodium acetate*, red crystals of chromous acetate. R. Stahn studied the reduction of *chloroacetic acid* and of *oxalic acid;* and A. Moberg found that *potassium oxalate* gives a grey bluish-green precipitate; *sodium formate* has no visible action; *potassium tartrate* has no action; *sodium citrate* gives a violet-red precipitate which slowly dissolves; *potassium succinate* gives a scarlet-red precipitate; *potassium benzoate*, a pale red precipitate; and *sodium tetraborate*, a pale blue precipitate. R. Stahn studied the reduction of *benzaldehyde*. A. Moberg observed that *potassium hydroxide* gives a yellow precipitate, and, added E. M. Péligot, if kept out of contact with air it gives a brown precipitate of hydrated chromous oxide (*q.v.*) accompanied by the evolution of hydrogen. W. Traube and co-workers found that the precipitation of soln. of chromous salts by alkali-lye gives a mixture of hydrated chromous and chromic oxides in varying proportions. E. M. Péligot regarded chromous chloride as one of the most powerful of reducing agents. For instance, it gives a brown precipitate of chromic chromate when treated with *potassium monochromate; cupric salt* soln. furnish first cuprous chloride, and afterwards with an excess of chromous salt, a red precipitate of cuprous oxide or copper; E. Zinth and G. Rienäcker studied the electrometric titration of salts of copper, silver, and gold with chromous chloride. According to E. M. Péligot, gold is precipitated from a soln. of *gold trichloride*, and the reaction is accompanied by an evolution of hydrogen; and *mercuric chloride* furnishes mercurous chloride. H. Brintzinger and F. Oschatz followed the electrometric titration of *molybdic acid* with chromous chloride down to the formation of tervalent molybdenum; and H. Brintzinger and F. Rodis, alloys of tin and antimony, copper and tin, and bismuth and tin. N. H. Furman titrated chromous salts with soln. of ceric sulphate. E. M. Péligot found that *tungstic acid* is reduced to the blue lower oxide; and H. Löwel obtained tin from a soln. of *stannous chloride*. E. Zinth and G. Rienäcker studied the electrometric titration of salts of mercury, bismuth, and iron with chromous chloride.

As indicated above, H. Moissan obtained what he regarded as a *hexahydrate* by evaporating aq. soln. of chromous chloride; but A. Recoura, G. Baugé, and W. A. Knight and E. M. Rich showed that the product is the tetrahydrate, $CrCl_2.4H_2O$, and they recommended the following mode of preparation:

> Chromous acetate is dissolved in conc. hydrochloric acid in vacuo, and the clear soln. is boiled down to dryness. If this distillation is too prolonged, or if it is interrupted overnight, the dark green isomeride is usually formed, whilst if the temp. rises above 51° after crystals have begun to appear, the product is pale blue or light green or white, but these are varieties of the blue isomeride, and are finally converted into the stable dark blue hydrate in presence of cold water. The blue crystals are washed by repeated decantation with pure acetone, and the final drying carried out with ether.

The blue crystals of the tetrahydrate readily absorb oxygen from air to form a greenish-black oxychloride. W. A. Knight and E. M. Rich showed that the blue crystals prepared in this way appear to undergo no alteration when left for many months, but, in spite of the high degree of purity of this chromous chloride (especially when it has been reprecipitated from sat. soln. by conc. hydrochloric acid), its soln., on exposure to the air, has a markedly disagreeable odour. Water, not hydrogen chloride, is evolved when the hydrated salt is heated in vacuo at 180°. T. Döring found that the transformation of soln. of chromous chloride into chromic chloride is catalytically accelerated by platinum, gold, silicic acid, etc. J. W. McBain also studied the catalytic decomposition in the presence of colloidal platinum. M. Prud'homme showed that chromous chloride is green in hot, conc. soln., although its cold, dil. soln. is blue, and hence, by analogy with the chromic salt, he inferred that two isomeric forms exist in aq. soln. J. W. McBain isolated a dark green chromous chloride which gave a green soln. with water, but the soln. soon became azure-blue. The change from a green to a blue soln. occupies only a few seconds in neutral soln. at ordinary temp., but in acidic soln. the change is so retarded that it may require weeks for its completion. If the change from blue to green were due to a partial hydrolysis resulting in the formation of a green $Cr(OH)^{\cdot}$-cation, then it is difficult to explain M. Prud'homme's observation that conc. hydrochloric acid favours the formation of the green colour. The assumption that the change is due to a partial dissociation resulting in the formation of stable $CrCl^{\cdot}$-cation which colours the liquid green is supported by W. A. Knight and E. M. Rich's observation that the presence of a large proportion of another chloride favours the green colour. Observations on the f.p. of the green and blue soln. show that it is probable that the blue soln. furnishes three ions: $CrCl_2 \rightleftharpoons Cr^{\cdot\cdot} + 2Cl'$, while the green soln., being less ionized, furnishes two ions: $CrCl_2 \rightleftharpoons CrCl^{\cdot} + Cl'$.

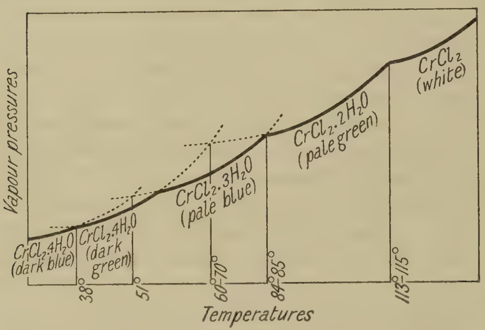

FIG. 73.—Diagrammatic Relation between Temperature and, say, Vapour Pressure of the Hydrated Chromous Chlorides.

W. A. Knight and E. M. Rich showed that if water be pumped from the tetrahydrate at 50°, a mixture of pale blue *trihydrate*, $CrCl_2.3H_2O$, and light green dihydrate is formed, but when water is added, the light green hydrate becomes pale blue trihydrate. The flask and contents are then heated to 51°, and the pale blue trihydrate is quickly dried at ordinary temp. by evacuation through a phosphorus pentoxide tube. The light green *dihydrate*, $CrCl_2.2H_2O$, is formed when water is pumped from the tetrahydrate between 70° and 80°; evacuation at 100° has no further effect. The dark blue tetrahydrate is the stable form up to 38°, when it passes into the dark green tetrahydrate; but if the dark green tetrahydrate does not appear, the dark blue modification is stable up to 51°, at which it passes into the pale blue trihydrate; the dark green tetrahydrate is stable between 38° and 60°–70°, when it forms the light green dihydrate. The pale blue trihydrate is converted into the light green dihydrate at 84°–86°, and this, in turn, becomes the white anhydrous chloride at 113°–115°. Fig. 73 represents the relationship between, say, the vap. press. or the conc. of sat. soln. and temp. The metastable regions are represented by dotted lines. The observed vap. press., p mm., with sat. soln. were

	25°	35°	45°	48°	49°	50°	55°	60°	65°
p . .	2·9	8·0	19·0	25·0	27·6	28·8	39·7	56·0	78·4
	$CrCl_2.4H_2O$					$CrCl_2.3H_2O$			

There is a definite break in the curve at 49°, which is close to the 51° obtained by observations on the change of colour.

L. N. Vauquelin [2] evaporated a soln. of chromic oxide in hydrochloric acid to dryness and heated the product to expel the last traces of water. H. Rose said that the last traces of water cannot be expelled without forming chromic oxide which colours the mass green. J. J. Berzelius, and H. F. Gaultier de Claubry heated the residue to a high temp. when a large proportion sublimed as **chromic chloride,** or **chromium trichloride,** $CrCl_3$. H. Rose, and H. Löwel obtained the anhydrous chloride by heating the hydrated salt, obtained by evaporating an aq. soln. of the chloride, in a current of dry chlorine so that chromium trichloride sublimes. F. Wöhler found that heated chromium burns in chlorine forming violet chromium trichloride. H. Moissan said that the reaction occurs at 600°. J. Y. Johnson heated ferrochromium in chlorine gas with or without a reducing agent like carbon monoxide. Heat is required to start the reaction, but thereafter the temp. is controlled by varying the amount of chlorine so that iron chloride is sublimed. F. Wöhler, and C. E. Ufer also obtained this chloride by passing dry chlorine over an intimate mixture of chromic oxide and carbon. H. Moissan heated to 400° chromic oxide, which had not been previously calcined, in dry chlorine gas, and A. Vosmär applied the reaction to the opening up of ferrochromium for analysis. F. M. Jackson heated ferrochrome in chlorine at above 350° to volatilize the ferric chloride, and then to 650° to produce chromic chloride. R. D. Hall obtained the trichloride by heating chromic oxide in a current of sulphur monochloride vapour; C. Matignon and F. Bourion used a mixture of sulphur monochloride and chlorine with the chromic oxide at 400°; F. Bourion preferred sulphur dichloride. J. R. Mourelo considered this to be the best mode of preparation. E. Demarçay passed carbon tetrachloride vapour over chromic oxide to obtain chromic chloride—P. Camboulives recommended a temp. of 580°. G. Rauter observed that when chromium trioxide or a chromate is heated in the vapour of silicon tetrachloride, chromic chloride is formed; and A. Michaelis found that it is formed by the action of phosphorus trichloride on chromyl chloride. H. Quantin prepared chromic chloride by heating chromyl chloride in a current of carbon monoxide, or of carbon tetrachloride; and M. Prud'homme worked with the materials in a sealed tube at 200°. F. P. Venable and D. H. Jackson found that the chlorination of chromic oxide with a mixture of chlorine and carbon monoxide starts at 625°. P. Curie passed the vapour of carbon disulphide mixed with hydrogen chloride over heated chromic oxide; and J. J. Berzelius, C. E. Ufer, F. Serena, and L. R. von Fellenberg passed chlorine over heated chromium sulphide.

Chromic chloride, according to H. Rose, furnishes micaceous, puce or violet laminæ. Like talc, they leave a mark on the skin. The colour of chromic chloride becomes very much paler at liquid air temp. G. Natta found that chromic chloride crystallizes in the trigonal system—probably holohedral. The X-radiograms show that the unit cell has a side $a=4{\cdot}42$ A.; the axial ratio $a : c=1 : 1{\cdot}29$ or $1{\cdot}30$; and contains one mol. of $CrCl_3$ per unit cell; and the calculated sp. gr. is 2·71. On the other hand, N. Wooster found that the unit cell contains six molecules, the chlorine atoms being arranged in cubic close-packing, and the chromium atoms occupy octahedral positions. The parameter $a=6{\cdot}0$ A., and $c=17{\cdot}5$ A. A. Schafarik gave 3·03 for the sp. gr.; F. W. Clarke and J. P. Grabfield gave 2·757 at 15°/4°; and W. Biltz and E. Birk, 2·784 at 25°/4°. M. Crespi found the sp. gr. of the anhydrous salt heated at 100° in dry air is 2·916. It is difficult to dry the substance, and it absorbs water greedily. The absorption resembles the process of adsorption of gases by glass. The mol. vol. of the contained water increases with the quantity of water retained by the salt. L. F. Nilson and O. Pettersson found the *vapour density* (air unity) to be 6·13 at 1065°; 5·51 at 1191°; 5·42 at 1277°; 4·82 at 1347°; and 4·58 at 1350°–1400°, when the theoretical value for $CrCl_3$ is 5·478. Hence, the simple formula $CrCl_3$ represents the molecule in the state of vapour; above 1300°, dissociation sets in: $2CrCl_3 \rightleftharpoons 2CrCl_2+Cl_2$. A. Scott confirmed these results. P. Fireman and E. G. Porter said that the dissociation, indeed, can be detected at 355°, for when an inert gas is passed over the chloride at that temp. and then through a soln. of potassium iodide, iodine is set free by the chlorine. F. Ephraim gave for the dissociation press., *p*, for $2CrCl_3 \rightleftharpoons 2CrCl_2 + Cl_2$, 205 mm. at 885°; 209 mm. at 902°; 415 mm. at 920°; 535 mm. at 930°; and 605 mm. at 933°. The results, however, are complicated by the volatility of the chromium chloride. H. Kopp gave 0·143 for the *specific heat.* K. Jellinek and R. Koop gave for the *vapour pressure:*

	700°	800°	900°	1000°
P . .	0·0187	0·0618	0·1845	0·366 atm.

A. Recoura gave for the heat of formation: $CrCl_{2soln.} + Cl_{gas} = CrCl_{3soln.} + 56·7$ Cals. K. Jellinek and R. Koop gave for the reaction $2CrCl_2 + Cl_2 = 2CrCl_3 + 66·95$ Cals.; and for $Cr + 1·5Cl_2 = CrCl_3$, 110·18 Cals. O. Stelling studied the X-ray absorption spectrum; C. P. Snow and F. I. G. Rawlins, the colour; and P. Krishnamurti, the Roman effect. W. Hampe found that the *electrical conductivity* of the trichloride is very small. T. Peczalsky and J. Cichocky studied the effect of chromic chloride on the thermionic emission of copper. S. Meyer gave 34×10^{-6} mass units for the *magnetic susceptibility* of chromic chloride at 18°; E. Feytis gave $44·1 \times 10^{-6}$ mass units; and for the atomic magnetism, R. H. Weber gave 0·00631. H. R. Woltjer, and H. R. Woltjer and H. K. Onnes observed that the susceptibility of chromic chloride decreases with the strength of the magnetic field at the temp. of liquid hydrogen; and for a given field strength, the susceptibility increases with falling temp. The observed data down to 64° K. follow the relation $\chi(T\text{-}32·5)$=constant, where χ denotes the susceptibility and T the absolute temp. For the aq. soln., G. Quincke gave the magnetic susceptibility 40×10^{-6} mass unit at 19°; S. Ishiwara gave $44·3 \times 10^{-6}$ mass unit at 18·5°; and G. Jäger and S. Meyer, 47×10^{-6} mass unit at 19°.

A. Moberg, and E. M. Péligot observed that when *hydrogen* is passed over the heated chromic chloride, chromous chloride is formed, and J. J. Berzelius, and A. Moberg noted that at a higher temp. chromium is produced; K. Jellinek and R. Koop, that the reduction of chromic chloride by hydrogen proceeds $2CrCl_3 + H_2 \rightleftharpoons 2CrCl_2 + 2HCl$ between 416° and 510°, and $CrCl_2 + H_2 \rightleftharpoons 2HCl + Cr$ between 1021° and 1192°. V. N. Ipatieff and B. A. Mouromtseff found that a soln. of the chloride is reduced by hydrogen at 200 atm. press. H. Rose observed that when heated in *air,* chromic chloride is quietly reduced to the oxide. J. Y. Johnson converted the anhydrous salt into the hydrate without the aid of a reducing agent as catalyst by exposing an aq. suspension to the action of a cathodically polarized conductor, *e.g.* in a lead-lined iron vessel having a chromium anode and using a very low current density. The heat generated in the process enables a highly conc. soln. to be produced, which is filtered while hot and solidifies on cooling. H. Kunheim said that when heated in *water vapour,* chromic chromate is formed; and F. Bourion found that when heated in *oxygen* mixed with water vapour, chromic oxide is produced. For the solubility in water, *vide infra.* R. Schwarz and G. Meyer observed that anhydrous chromic chloride does not take up *hydrogen chloride.* A. Recoura found that if hydrogen chloride be passed for some days into a soln. of chromic chloride, the liquid gradually becomes brown or brownish-red, owing to the formation of a **chromic hydrochloride.** If ether be added, a green, unstable precipitate approximating $CrCl_3.HCl$ is formed. A. W. Cronander obtained a blue complex **chromic phosphoctochloride,** $CrCl_3PCl_5$, by the action of *phosphorus pentachloride* on chromic or chromyl chloride in a sealed tube at 150°. R. F. Weinland and C. Feige, and P. Pfeiffer prepared a complex with *antimony pentachloride,* namely, **chromium antimonioctochloride,** $CrCl_3.SbCl_5.10H_2O$, in green leaflets, and **chromium triantimoniododecachloride,** $CrCl_3.3SbCl_3.13H_2O$, in violet-grey needles. R. F. Weinland and H. Schmid obtained $Cr[SbCl_6]_3.15H_2O$, and also $[SbCl_6].CrCl_2.10H_2O$—*vide* antimony pentachloride, **9.** 52, 18. H. Rose said that puce-coloured chromic chloride is extraordinarily resistant towards acids. According to L. R. von Fellenberg, boiling *hydrochloric*, or *nitric acid*, or *aqua regia* does not act on the chloride, but N. Bunge found that if a little sodium amalgam be added to dil. hydrochloric acid in which the trichloride is suspended, a green soln. and some chromium amalgam are formed. H. Rose observed that conc. *sulphuric acid* can be distilled from the puce-coloured chloride, but J. Pelouze added that with hot, conc. sulphuric acid, chlorine is slowly given off, leaving behind a green mass miscible with water. Molten *sulphur* was found by J. L. Lassaigne, and J. J. Berzelius, to furnish chromium sulphide ; J. von Liebig noted that when heated in *hydrogen sulphide*, chromium sulphide is formed ; H. Moissan said that *ammonium chloride* at a red-heat forms chromous chloride ; A. Schrötter, that *ammonia* converts it into nitride. J. Persoz studied the action on chromic chloride. Neither aq. ammonia nor ammonia gas acts on violet chromic trichloride, but W. R. Lang and C. M. Carson found that the puce trichloride reacts with liquid ammonia forming a yellow powder from which water extracts **chromic hexamminochloride,** $CrCl_3.6NH_3.H_2O$, and also **chromic pentamminochloride,** $CrCl_3.5NH_3$; while W. R. Lang and E. H. Jolliffe obtained with *methylamine* the complex **chromic pentamethylaminochloride,** $CrCl_3.5(CH_3)NH_2$; and with *ethylamine*, **chromic pentaethylaminochloride,** $CrCl_3.5(C_2H_5)NH_2.H_2O$, whilst, at 60°, it forms **chromic tetraethylaminochloride,** $CrCl_3.4(C_2H_5)NH_2.H_2O$; *ethylenediamine* forms **chromic tetraethylenediaminochloride,** $CrCl_3.4C_2H_4(NH_2)_2.H_2O$; while *dimethylamine, diethylamine, trimethylamine, triethylamine, aniline, methylaniline*, and *dimethylaniline* have no action on chromic chloride. P. Pfeiffer obtained a salt with *pyridine*, namely, **chromic tripyridinochloride,** $CrCl_3.3C_5H_5N$—*vide infra*, ammines. G. Fuseya and K. Murata observed the complexes are formed with *glycine ;* and H. Farl, with pyridine and chromic dichloroethylate. G. M. Bennett and E. E. Turner studied the reaction with *magnesium phenyl bromides :* $2CrCl_3+2(C_6H_5)MgBr=C_6H_5.C_6H_5+2CrCl_2+MgCl_2+MgBr_2$, etc. F. Hein obtained chromium phenyl bromide, $Cr(C_6H_5)_5Br$, as a product of this reaction. H. Rose found that *phosphine* produces the phosphide. I. Koppel said that the puce-coloured, anhydrous chloride does not dissolve in *ethyl alcohol*, but it does so if a piece of magnesium, zinc, or chromium be present, or if a trace of chromous acetate be added. According to L. C. A. Barreswill, when chromic chloride and alcohol are heated in a sealed tube, ethyl chloride is formed. F. Pintus, and I. Koppel obtained **chromium alcoholatochloride,** $CrCl_3.3C_2H_5OH$, in red needles—*vide infra*, ammines. P. A. Thiessen and B. Kandelaky examined these salts. P. Rohland said that puce-coloured chromic chloride is practically insoluble in absolute ethyl alcohol, *methyl alcohol, acetaldehyde*, and in *ether.* W. Eidmann found it to be insoluble in *acetone ;* and H. Arctowsky, in *carbon disulphide.* A. Naumann said that the puce-coloured chloride is sparingly soluble in *methyl acetate ;* and that the yellow form is slightly soluble in *benzonitrile.* L. Hackspill found that *calcium* reduces heated chromic chloride to chromium ; F. Wöhler, that zinc, in molten potassium chloride, reduces it to chromium ; L. R. von Fellenberg, and H. Rose said that the puce-coloured chloride is insoluble in dil. alkali-lye, and that it is decomposed by boiling conc. soln. of *alkali hydroxides and carbonates ;* A. Geuther, that it reacts with chromium trioxide: $3CrO_3+2CrCl_3=Cr_2O_3+3CrO_2Cl_2$; and with molten *potassium dichromate :* $3K_2Cr_2O_7+2CrCl_3=Cr_2O_3+6KCrO_3Cl$. F. Wöhler obtained crystalline chromic oxide by fusing the trichloride with *sodium carbonate* and ammonium chloride.

According to N. Bunge, C. W. Vincent, and Z. Roussin, a slightly acidified soln. of chromic chloride or other chromium salt yields with **sodium-amalgam** an easily decomposable chromium amalgam. A. Commaille observed that **magnesium** precipitates only hydrated chromic oxide from a soln. of chromous or chromic chloride. K. Someya found that soln. of chromic salts are quantitatively reduced to chromous salts by **zinc-amalgam** or **lead-amalgam;** and C. Boulanger studied the reduction with **zinc** and with **aluminium**. According to T. Peczalsky, when a **copper** rod has its lower half surrounded by chromic chloride, cementation is produced throughout its length, specially on the portion in contact with the salt. Metallic chromium was deposited on the rest of the rod, whilst rhombohedric copper crystals were found in the salt. If the rod was contained in exhausted "pyrex" tubes, surrounded by chlorides of copper, nickel, or chromium, deposits of copper were found to have penetrated the glass after 5–10 hrs. at 600°–800°.

H. Rose said that the anhydrous, puce-coloured chromic chloride is insoluble in cold water; and E. M. Péligot, that it is insoluble in boiling water. J. Pelouze added that it is very slowly soluble in cold water, but water at 150°–200° forms a deep green soln. H. Moissan also obtained an aq. soln. by heating the chloride with water in a sealed tube at 180°. According to E. M. Péligot, while chromic chloride is insoluble in cold water, yet, when in contact with chromous chloride, it dissolves with ease, heat being evolved, and a green soln. formed. The soln. has all the characteristics of chromic salts. A very small quantity, less than 0·000001 per cent. of chromous chloride, suffices to render chromic chloride soluble.

A. Moberg, and K. Drucker found that the dissolution of chromic chloride is facilitated by the presence of dil. acid and zinc; K. Drucker, aluminium, ferrous oxalate; a soln. of copper in cuprous sulphate, a soln. of arsenious acid and sodium hydrocarbonate or hydrogen in the presence of colloidal platinum at ordinary temp.; J. Pelouze, stannous, ferrous, or cuprous chloride, or sodium thiosulphate; V. A. Jacquelin, titanous chloride, or sulphur dioxide; H. Moissan, chromous bromide or iodide; and P. Rohland, hydrogen at 90°; and the following metals in contact with the chromic chloride have a decreasing order of activity in facilitating the dissolution of the salt: potassium, sodium, magnesium, aluminium, zinc, cadmium, tin, iron, nickel, lead, antimony, bismuth, copper, mercury, and silver—while platinum and gold are inactive. M. Bauck noticed that a piece of chromic chloride deliquescing on tinfoil forms a green spot presumably owing to the formation of a little chromous chloride by the reducing action of the tin. P. Rohland found that in methyl or ethyl alcohol, or acetone soln., the activity of chromous chloride in promoting the dissolution is less than in aq. soln.

E. M. Péligot, and J. J. Berzelius said that the chromous chloride acts as a contact catalyst; and L. C. A. Barreswill assumed that the chromous chloride forms with violet chromic chloride a double salt which decomposes into chromous chloride and a green soluble chromic chloride. H. Löwel supposed that the chromous chloride reduces the violet chromic chloride and at the same time is transformed into soluble chromic chloride, and the reaction continues anew. A. Recoura's hypothesis was somewhat similar to this. P. Rohland said that the action is not catalytic, but that it favours the dissolution of the chromic chloride by its reducing action. A considerable proportion of stannous chloride is required to do this work, and that indicates that the action is not a characteristic of catalyzed reactions. K. Drucker measured the rates of dissolution in the presence of various reducing agents—*vide supra.* He found that the rate is dependent upon (i) the nature of the reducing agent, (ii) its reduction-potential, increasing and decreasing with this, and (iii) its absolute conc. In the presence of a sparingly soluble reducing agent, the dissolution of the chromic chloride takes place provided that the agent is also present in the solid state. The function of the reducing agent does not appear to be entirely catalytic, but a reaction takes place between this and the chromic chloride. The dissolution is probably preceded by a slight reduction to chromous chloride, the catalytic influence of which is very great; only a small quantity of this can, however, be formed, since its potential in soln. of appreciable conc. is greater than that of hydrogen, whilst the potential in the soln. cannot rise above that of the reducing agent present. It has not been proved that the catalytic influence is wholly due to chromous chloride. E. Hein and co-workers studied some complexes with organic radicles.

The hydrated chromic chlorides are perhaps the most peculiar hydrated salts in inorganic chemistry. There are one tetrahydrate, three isomeric hexahydrates —violet, pale green, and dark green—and one decahydrate; and, as indicated below, the dehydration of the dark green hexahydrate furnishes a *hemihydrate*, $CrCl_3.\frac{1}{2}H_2O$, and a *hemitrihydrate*, $CrCl_3.1\frac{1}{2}H_2O$.

The tetrahydrate, $CrCl_3.4H_2O$.—L. Godefroy[3] prepared this salt by allowing the dark green hexahydrate to stand over conc. sulphuric acid in vacuo. The pale green powder readily takes up 2 mols. of water to form the hexahydrate, with the evolution of heat—according to G. O. Higley—eq. to 83·96 Cals. A. Werner and A. Gubser showed that the tetrahydrate can also form double salts with 2 mols. of, say, alkali chloride. The aq. soln. of the tetrahydrate is identical with the aq. soln. of the dark green hexahydrate. A. E. Lindh studied the X-ray absorption spectrum. The mol. conductivity of the aq. soln., rapidly determined at 0°, is 49 at a dilution v=125—the conductivity increases to the value for the dark green hexahydrate after it has stood for some time. The arguments with respect to the constitution of the dark green hexahydrate (*q.v.*) are applicable to this salt. The 4 mols. of water are considered to be constitutional because they are not removed by drying. This means that the tetrahydrate can be regarded as **chromic dichlorotetraquochloride,** $Cr[Cl_2(H_2O)_4]Cl$.

The dark green hexahydrate, $CrCl_3.6H_2O$.—This salt was prepared by A. Moberg, and E. M. Péligot by evaporating the green soln. in vacuo; the green soln. used by the latter was obtained by dissolving the puce-coloured anhydrous chloride in water containing a trace of chromous chloride. P. Rohland prepared the salt in a similar way. H. Rose obtained the green soln. by boiling chromic acid in hydrochloric acid, or by dissolving hydrated chromic oxide in that acid; E. M. Péligot, by evaporating a mixture of lead chromate and hydrochloric acid, and extracting the chromic chloride with alcohol, or from the clear soln. obtained by digesting lead chromate with alcohol and hydrochloric acid; L. Godefroy sat. with chlorine a soln. of 3 parts of potassium dichromate in 7 parts of alcohol. The soln. was filtered through cotton-wool, and the filtrate distilled until it separated into two layers. On cooling, the green lower layer solidified to a mass of crystals which were purified by recrystallization from a small quantity of water. The crystals thus obtained are thin lozenge-shaped lamellæ which readily give off some of their water, but can be preserved in a closed vessel. A. Recoura, N. Bjerrum, and A. Werner and A. Gubser passed hydrogen chloride into a sat. soln. of chromic chloride prepared from chromium trioxide and hydrochloric acid, when crystals which have been variously described as green, or emerald-green needles or plates were obtained; R. F. Weinland and A. Koch, and A. Johnsen said that the crystals are six-sided, biaxial, monoclinic or triclinic plates; and J. Olie described them as doubly refracting, rhombic or pseudohexagonal plates. W. Biltz and E. Birk gave 1·835 for the sp. gr. at 25°/4°; and 145·2 for the mol. vol. The hygroscopic crystals were said by A. Werner and A. Gubser to have an intensely sweet taste. The analyses of A. Moberg, and A. Recoura gave rather different values for the amount of water of crystallization, but the analyses of E. M. Péligot, L. Godefroy, and A. Werner and A. Gubser agree with the formula $CrCl_3.6H_2O$. A. Werner and A. Gubser found that 2 mols. of water are readily withdrawn when the salt is confined over sulphuric acid in vacuo, but no more water is lost. On the other hand, J. Olie said that more than this amount of water can be removed because after long standing over sulphuric acid in vacuo at 15°, the surface of the salt becomes pale red. When heated for 6 hrs. at 100°, rather more than 4 mols. of water are expelled. The product is dark violet; it readily absorbs water from the atm.; and forms a soln. almost identical in appearance and behaviour with the original green salt. Some hydrogen chloride, however, was also given off under these conditions. N. Bjerrum observed that when the salt is kept for 4 months over phosphorus pentoxide, under 1 mm. press., there remains the red hemitrihydrate, $CrCl_3.1\frac{1}{2}H_2O$, which forms a yellowish-green soln. with water, changing to the violet-blue colour

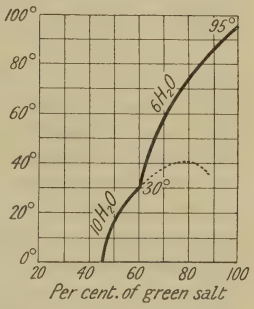

Fig. 74.—Solubility of Green Chromic Chloride in Water.

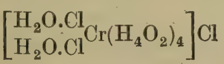
of the aq. soln. of green chromic chloride. J. Olie found that the natural m.p. of the salt—with 36 per cent. of the violet isomer—is 83°, and the true m.p. is over 90°—*cf.* Fig. 76; the salt can be heated slowly to 100° in vacuo without melting. J. Olie gave 2·66 Cals. for the heat of transformation to the violet isomer. H. de Bois and G. J. Elias measured the effect of temp., and of a magnetic field on the absorption spectrum of solid chromic chloride. The electrical conductivity of the soln. of the hemitrihydrate is at first less than that of the soln. of the hexahydrate, but it increases rapidly after a few minutes. If the green hexahydrate be heated very slowly to 155°, in a current of hydrogen chloride, there remains the hemihydrate, $CrCl_3.\frac{1}{2}H_2O$, as red powder. A. Recoura found that the green hexahydrate is freely soluble in water, so that at 15° the sat. soln. has 56·6 per cent. of the salt. J. Olie inferred that at 25° a sat. soln. has 50 per cent. of the green salt, but in the process of dissolution some violet salt is formed, and the change from the green to the violet salt (*vide infra*) goes on slowly until equilibrium is attained in about 10 days; this is accompanied by an apparent increase in the solubility of the salt, because the violet salt is rather more soluble than the dark green salt. Thus, at 25°, the percentage solubility, *S*, and the percentage proportions of dark green and violet salts in soln., are:

Time .	0·25	0·5	4·0	24	48	154	456 hrs.
S .	58·36	59·39	63·27	68·50	68·42	69·01	68·58 per cent.
Green .	91·70	87·43	75·20	62·36	59·10	57·16	57·38 ,,
Violet .	8·30	12·57	24·80	37·64	40·90	42·84	42·62 ,,

J. Olie also observed that the formation of the decahydrate introduces a complication, because there is a transition point near 30° when the system contains about 32 per cent. of the violet salt and 68 per cent. of the green salt. If a soln. sat. at a temp. below 32° is cooled, only the decahydrate separates out; but if sat. above 32°, both hexahydrate and decahydrate separate on cooling. A. Werner and A. Gubser also found that at room temp. the decahydrate changes to its equilibrium form very slowly. J. Olie represented his results by a diagram resembling Fig. 74. E. N. Gapon studied the speed of hydration and dehydration and of the passage ot the green to the violet hydrate; and the mechanism of the charge, by L. Meunier and M. Lesbre. A. Recoura gave —0·04 Cal. for the heat of soln. of a mol of the green hexahydrate in 150 mols of water, but, according to J. Olie, this datum does not represent the heat of soln. of the green hexahydrate, but rather the heat of hydration to the decahydrate, and the heat of soln. of the decahydrate. O. Stelling studied the X-ray spectrum. E. Feytis observed that the magnetic susceptibility $23{\cdot}0 \times 10^{-6}$ mass unit is very little different from the value for the violet salt. R. H. Weber made observations on this subject. E. Feytis gave for the mol. susceptibility 6179×10^{-6}, and J. B. Elias, 6100×10^{-6}. N. Bjerrum found that the dark green hexahydrate is soluble in fuming hydrochloric acid; A. Werner and A. Gubser, that it is freely soluble in alcohol, sparingly soluble in acetone, and insoluble in ether; and P. Rohland, that it is nearly insoluble in ether, and freely soluble in methyl and ethyl alcohols as well as in acetaldehyde. The salt is largely ionized in methyl alcoholic soln., but the mol. wt. is normal in ethyl alcohol and in acetone soln. The formation of the salt was also studied by L. Meunier and M. Lesbre. From the properties of the soln., indicated below, A. Werner and A. Gübser regarded the dark green hexahydrate as **dihydrated chromic dichlorotetraquochloride,** $[CrCl_2(H_2O)_4]Cl.2H_2O$, with 2 masked chlorine atoms; the hypothesis is based on the behaviour of the salt on drying; on treatment with silver nitrate; and on the electrical conductivity of aq. soln.—*vide infra.* They also represented it by the formula $[(H_2O.Cl)_2Cr(H_2O)_4]Cl$.

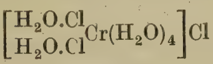
The pale green hexahydrate, $CrCl_3.6H_2O$.—This salt was prepared by N. Bjerrum by pouring a hydrochloric acid soln. of chromic chlorosulphate into ether sat. with hydrogen chloride; and by boiling a soln. of 13·4 grms. of chromic dichlorotetraquochloride in 18 grms. of water for 10 mins., then sat. the soln. at 8°–10° with hydrogen chloride ; the filtered liquid was then poured into 200 c.c. of ether sat. with hydrogen chloride at 10°, while hydrogen chloride is passing through the liquid. The salt separates out when the soln. is allowed to stand, and it is washed with ether sat. with hydrogen chloride. The pale green hexahydrate is supposed to be present in aq. soln. containing the other two chlorides, and is said to be a maximum when the green dichlorotetraquochloride is dissolved in its own weight of water, and the soln. boiled for 10 mins.—*vide infra.* G. O. Higley obtained it by heating the violet salt to 70° ; and by evaporating a soln. of the green chloride and hydrochloroplatinic acid, he obtained the salt $[Cr(H_4O_2)_5Cl]PtCl_6$. A. del Campo and co-workers obtained this salt by saturating with hydrogen chloride an aq. ethereal soln. of green chromic chlorosulphate, $[CrCl(H_2O)_5]SO_4.H_2O$. The pale green hexahydrate was also prepared by A. Werner and R. Huber, and by R. F. Weinland and T. Schumann. W. Biltz and E. Birk found the sp. gr. to be 1·760 at 25°/4°, and the mol. vol. 151·4. According to N. Bjerrum, the pale green, microcrystalline powder is very hygroscopic, and it slowly passes into the dark green salt. It is soluble in a mixture of equal vols. of fuming hydrochloric acid and ether forming a green soln., which, when poured into an excess of ether sat. with hydrogen chloride, deposits the pale green solid. The pale green hexahydrate forms a bluish-green soln. with water, and the colour slowly changes to bluish-violet ; it is soluble in alcohol, and in acetone. Conc. sulphuric acid precipitates from the aged aq. soln., $CrClSO_4.6H_2O$. This behaviour of the salt together with its behaviour towards silver nitrate, and the conductivity of its aq. soln., suggests that the salt is **hydrated chromic chloropentaquodichloride,** $[Cr(H_2O)_5Cl]Cl_2.H_2O$, with one masked chlorine atom.

The decahydrate, $CrCl_3.10H_2O$.—L. Godefroy prepared this salt by placing a sat. soln. of the dark green hexahydrate in vacuo for several days at a temp. below 6°. A. Werner and A. Gubser obtained it by cooling, by means of a freezing mixture, a soln. of the dark green hexahydrate in half its weight of water ; and J. Olie, by triturating the dark green hexahydrate with the theoretical proportion of water. L. Godefroy described the salt as forming green, triclinic crystals, which readily lose water. Over sulphuric acid, for example, they lose 4 mols. of water, and become opaque and friable. The salt melts slowly in its water of crystallization at a temp. above 6° or 7°. J. Olie found that when rapidly heated, the salt melts at 32°. This temp., however, is not a m.p., but rather a transition temp.—*vide* Fig. 74—A. Werner and A. Gubser found that the decahydrate is freely soluble in water, alcohol, and acetone. G. O. Higley found that the heat of soln. is zero ; but in conc. soln., J. Olie found that the heat of soln. is negative. N. Bjerrum's observations on the extinction coeff. of the soln. are summarized in Fig. 75. The mol. conductivity of a fresh $0·00988M$-soln. at 25° is 208·5 mhos, a value which is mean between those obtained for soln. of the dark green and the violet hexahydrates of the same conc. The hydrolysis constant, $K=8\times10^{-6}$ nearly, is about one-tenth the value for the violet salt. The conc. aq. soln., with conc. sulphuric acid, forms the chlorosulphate, $CrClSO_4.6H_2O$, or $[CrCl(H_2O)_5]SO_4.H_2O$. According to A. Werner and A. Gubser, the mol. conductivity, and the behaviour of the salt towards silver nitrate indicate that it contains two non-ionizable chlorine atoms ; and it behaves like **hexahydrated chromic dichlorotetraquochloride,** $[Cr(H_2O)_4.Cl_2]Cl.6H_2O$. Two of the ten mols. of water can be replaced by metal chlorides. It is assumed that four of the mols. of the hexahydrate are doubled. The tetrahydrate, dark green hexahydrate, and the decahydrate all give aq. soln. of identical properties ; and this when the soln. is freshly prepared before they have had time to undergo the slow changes indicated below. Consequently, deca-, hexa-, and tetra-hydrates are supposed to be similarly constituted : either $[Cr(H_2O)_4Cl_2]Cl$, $[Cr(H_2O)_4Cl_2]Cl.2H_2O$, and $[Cr(H_2O)_4Cl_2]Cl.6H_2O$, or else



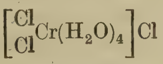
$$\left[\begin{matrix}H_2O.Cl\\H_2O.Cl\end{matrix}Cr(H_4O_2)_4\right]Cl$$

Decahydrate



$$\left[\begin{matrix}H_2O.Cl\\H_2O.Cl\end{matrix}Cr(H_2O)_4\right]Cl$$

Hexahydrate.



$$\left[\begin{matrix}Cl\\Cl\end{matrix}Cr(H_2O)_4\right]Cl$$

Tetrahydrate.

G. Quincke gave 1·2030 for the sp. gr. of a 20·8 per cent. soln. of $CrCl_3$ at 19°/4°. H. C. Jones and H. P. Bassett found the sp. gr. of soln. with M mols of the salt per litre at 18° to be :

M . .	0·05	0·1	0·2	0·4	0·6	0·9	1·5	2·25
Sp. gr. .	1·0099	1·0142	1·0258	1·0507	1·0773	1·1117	1·1806	1·2631

E. Moles and M. Crespi gave 1·802 for the sp. gr. and 147·5 for the mol. vol. According to W. Biltz and E. Birk, the mol. vol. of $[CrCl_2(H_2O)_4]Cl.2H_2O$ is 145·2 ; of $[Cr(H_2O)_6]Cl_3$, 148·1, and of $[CrCl(H_2O)_5]Cl_2.H_2O$, 151·4. The mol. vol. of the most stable of the chromic salts, the dark green dichlorotetra-aquochromic chloride dihydrate, $[CrCl_2(H_2O)_4]Cl.2H_2O$, is 145·2, that of the grey hexa-aquochromic chloride, $[Cr(H_2O)_6]Cl_3$, is 148·1, and that of the least stable, the light green monochloropenta-aquochromic chloride monohydrate, $[CrCl(H_2O)_5]Cl_2.H_2O$, is 151·4. The mol. vol. thus falls with increasing stability, as for organic isomerides, the difference for each pair being 2 per cent. The mol. vol. of chromous chloride hexahydrate is 129·6, and this corresponds with a volume of 14·5 for each mol. of water. The mol. vol. of the water in the chromic chloride hexahydrates are 14·7, 15·2 and 15·7, respectively, and the chromous chloride thus corresponds with the dark green chromic salt and may be formulated $[CrCl_2(H_2O)_4].2H_2O$. H. Lessheim and co-workers discussed the electronic structure. J. E. Howard and W. H. Patterson found that the effect of the dark green salt on the critical soln. temp. of binary mixtures of water with butyric acid, isobutyric acid, and phenol, and of ethyl alcohol and paraffin, is nearly twice that due to the violet salt for concentrations up to 0·05M ; above this conc., the difference becomes progressively smaller. H. C. Jones and H. P. Bassett found the lowering of the f.p. of aq. soln. of M mol of the salt per litre to be :

M .	0·05	0·1	0·2	0·4	9·6	0·9	1·5	2·25
F.p. .	−0·268°	−0·510°	−0·030°	−2·160°	−3·610°	−6·30°	−15·0°	−33·0°

Measurements were also made by G. Marchetti, and A. Werner and A. Gubser. The general results correspond with a mol. wt. nearly half the theoretical value 266·6. J. R. Partington and S. K. Tweedy observed that violet soln. of hexahydrated chromic chloride have a higher viscosity than analogous green soln., as would be anticipated from A. Werner's formulation of these salts. A. Recoura gave for the heat of the reaction $(CrCl_{3\text{green soln.}}.3NaOH_{\text{soln.}}) = 31·5$ Cals. at 10°, and the precipitated hydroxide dissolves in hydrochloric acid with the evolution of 20·7 Cals., or 20·6 Cals. according to E. Petersen ; the resulting soln. is blue. A. Piccini observed that the raising of the b.p. in methyl alcohol corresponds with a mol. wt. of about 50 ; in ethyl alcohol, 228 ; and in acetone, 271 ; the theoretical value is 266·6. F. Jost also obtained a mol. wt. of 33·2 in methyl alcohol. A. Recoura said that soln. appear green by reflected light, and red by transmitted light ; they found an absorption spectrum with a single green band ; a candle-flame viewed through such a soln. appears green ; but after the soln. has stood for 10 days a red band appears, and the flame finally appears to be reddish-violet. W. N. Hartley found that when anhydrous chromic chloride is dissolved in water, two kinds of salt are formed, one of which is precipitated by ammonium oxalate and the other not so. A soln. of the latter in thin layers at 20° shows a continuous

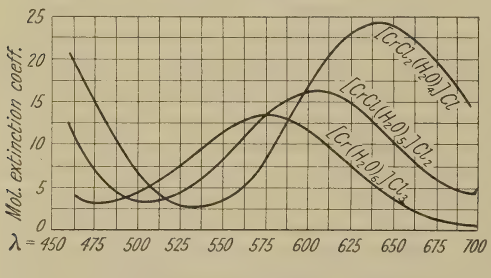


FIG. 75.—Molecular Extinction Coefficients of Solutions of the Chromic Chlorides for Light of Different Wave-lengths.

spectrum up to about λ=500 when bands appear at λ=704 to 685, and at λ=673 to 538. At 100°, the soln. is opaque. Observations were made by J. Formanek, W. Lapraik, J. M. Hiebendaal, J. L. Soret, H. W. Vogel, G. Magnanini, O. Knoblauch, A. Étard, H. C. Jones and J. A. Anderson, and H. C. Jones and W. W. Strong. N. Bjerrum found for the three hexahydrated chromic chlorides the mol. extinction coeff. illustrated by Fig. 75 for wave-lengths ranging from λ=450 to 700. The mol. extinction coeff., k, is defined by $I_0=I_e^{kml}$, where I_0 is the intensity of the incident light, and I the intensity after traversing a layer, l cm. thick, of a soln. with M mols per litre. In an analogous way, A. Byk and H. Jaffe measured the limits of absorption for ultra-violet rays ranging from λ=440 to 220, and found for the green soln. of the chloride (eq. to 5 grms. of chrome-alum for 100 c.c.) an absorption band λ=490 to 409·1 ; and for violet soln. bands λ=433·1 to 400·0, and λ=400·0 to 385·5. H. W. Vogel measured the absorption spectrum of alcoholic soln. ; and O. Stelling, the X-ray spectrum ; H. C. Jones and W. W. Strong, the effect of the presence of various other salts in the soln. of chromic chloride. N. Bjerrum found the mol. electrical conductivity, μ mhos, of aq. soln. with M mols per litre to be :

M . . .	0·00322	0·01074	0·00334	0·00998	0·0307	0·008
μ . . .	103·1	97·9	88·6	83·0	79·5	49·0

Observations were also made by A. Werner and A. Gubser, H. C. Jones and H. P. Bassett, H. C. Jones and C. A. Jacobsen, and A. B. Lamb. According to A. W. Speransky, the mol. conductivity of the soln. of the dark green salt, is about one-third of that of the violet salt. This, said A. Werner and A. Gubser, shows that a smaller proportion of ions is formed by the ionization of the salt, so that while the violet salt furnishes four ions per mol, the dark green salt yields only 2 ions. As the soln. of the green salt is allowed to stand, the ionization proceeds further, owing to the partial transformation of the green into the violet salt—*vide infra.* F. Jost gave for the mol. conductivity of soln. of the green salt in methyl alcohol, at room temp. :

M . . .	11·55	15·48	28·7	55·5	129·9
μ . . .	43·5	46·5	52·6	59·0	64·2 mhos.

H. C. Jones calculated for the percentage degree of ionization, α, and gave for the number of mols of water, H, in combination with a mol of the salt for soln. with M mols of salt per litre :

M . .	0·05	0·1	0·3	0·6	0·9	1·5	2·0	2·25
μ . .	52·7	46·9	38·1	31·2	25·6	16·9	11·6	9·6
H . .	117·9	66·6	42·5	39·2	31·8	26·0	22·1	20·2

L. G. Winston and H. C. Jones gave for the conductivity, λ, and the computed percentage ionization, α :

v	. .	4	8	32	128	512	1024	2048	4096
λ	0° .	86·30	104·53	130·03	162·34	188·46	200·21	214·48	229·73
	25° .	153·32	184·18	245·00	313·45	372·34	403·58	434·36	467·61
	35° .	199·10	243·55	319·15	393·62	465·10	504·31	543·02	586·16
α	0° .	37·6	45·5	56·6	70·7	82·1	87·2	93·3	100·0
	25° .	32·8	39·4	52·4	67·0	79·6	86·3	92·9	100·0
	35° .	34·3	42·0	55·0	67·9	80·2	86·9	93·6	100·0

H. M. Vernon estimated the degree of ionization from the colour of the soln. K. Hopfgartner's study of the transport numbers also led him to assume that the chromic ion is surrounded by a fairly large water sheath. F. L. S. Jones investigated the formation of complex anions in aq. soln.—*vide infra,* chromic sulphate. T. Murayasu studied the conductivity in soln. of the salt in glycine. N. Demassieux and J. Heyrovsky found that the polarization curve shows breaks at 0·7 and 1·35 volts, indicating that the electrochemical reduction occurs in two stages : $\mathrm{Cr}^{\cdot\cdot\cdot}\rightarrow\mathrm{Cr}^{\cdot\cdot}$, and $\mathrm{Cr}^{\cdot\cdot\cdot}\rightarrow\mathrm{Cr}$. The presence of an acid does not exert any influence on the deposition potential, and this is taken to mean that H˙-ions do not enter into the electrolytic process. It is also thought that the observations agree with the assumption that in conc. soln. the green chloride, $[CrCl_2(H_2O)_4]Cl.2H_2O$, is present; and that in dil. soln. the violet form, $[Cr(H_2O)_6]Cl_2$, predominates; and that it is easier to reduce the green complex than is the case with the violet.

According to E. Wiedemann, the atomic magnetism of chromium is about 42, when that of iron in ferric chloride is 42; and the result is independent of the anion associated with the chromium. Similar results were obtained by G. Jäger and S. Meyer. Observations on the subject were also made by E. Feytis, and R. H. Weber. E. Feytis gave for the mol. susceptibility 6181×10^{-6}; J. B. Elias, 5920×10^{-6}; and L. A. Welo found the susceptibility to be $22·6\times10^{-6}$ mass unit.

The co-ordination theory of the constitution of the hydrated chromic chlorides, said I. Koppel, *findet ihre stärkste Stütze in dem verschiedenen Verhalten der Chloridlösungen bei der Fällüng mit Silberion;* and A. B. Lamb and G. R. Fonda added that the application of the theory to the hydrated chromic chlorides is "perhaps the most striking exemplification of A. Werner's theory of molecular structure." The evidence lacks that decisive proof which would make the alternative hypotheses —*e.g.* the hydrolysis theory of their constitution—untenable. E. M. Péligot, and S. M. Jörgensen found that in the soln. of the dark green chloride two-thirds of the total chlorine is precipitated as silver chloride from newly prepared soln.; G. N. Wyrouboff said that five-sixths is so precipitated; while A. Werner and A. Gubser observed that at 0°, about one-third of the chloride is so precipitated—actually the amounts precipitated were rather greater than one-third. If the soln. are allowed to stand in contact with the silver salt, all the chlorine is ultimately precipitated as chloride. R. F. Weinland and A. Koch then showed that, using various silver salts as precipitants in the presence and in the absence of free acids, the proportion of chlorine precipitated depends on the nature and quantity of the particular silver salt employed. In the absence of acids, all the silver salts precipitated at least two-thirds of the chlorine as chloride; the presence of nitric acid diminished the proportion of precipitable chlorine; whereas silver salts of the weak acids—*e.g.* acetic, lactic, nitric or sulphuric acid—immediately precipitated all the chlorine. Silver salts of the strong acids—*e.g.* nitric, chloric, perchloric, or permanganic acid—did not precipitate all the chlorine as chloride, and the presence of strong acids suppressed the precipitation even more. A. Piccini also found that silver fluoride, like silver acetate, precipitated all the chlorine as chloride. He also found that a soln. of the dark green hexahydrate in ethyl alcohol or acetone gives up all its chlorine to an alcohol or acetone soln. of silver nitrate, whereas, with methyl alcohol soln., the results approximate to those obtained with water. J. Olie pointed out that R. F. Weinland and A. Koch used at least 3 eq. of silver salts and found at least two-thirds of the chlorine was precipitated; and he obtained similar results even with only 2·11 eq. of silver salt. J. Olie showed that the reaction $[CrCl_2(H_2O)_4]Cl.2H_2O \rightarrow [Cr(H_2O)_6]Cl_3$ is retarded or paralyzed by strong acids or H˙-ions; and he explained the fact that whilst the silver salts of strong acids precipitate only part of the chlorine, and silver salts of the weak acids precipitate nearly all the chlorine, owing to the removal of H˙-ions by the silver salts of the weak acids. The action of neutral salts, such as sodium and ammonium nitrates on precipitation by silver nitrate, is slight with small concentration, but a large amount of these salts greatly increases the proportion of chlorine thrown down. Strong acid at first cause a decrease in the proportion of chlorine precipitated until in certain concentrations only one eq. is affected; more conc. soln. cause an increase in the amount precipitated. Weak acids have a much smaller effect. The great effects of strong acids and neutral salts when present in considerable concentration is attributed to a direct exchange of the chlorine in the positive nucleus for other groups. A. B. Lamb said that the retarding action of the H˙-ions on the isomeric change can be explained by assuming that one stage of the process involves the hydrolysis of the dark green chromic salt, say, $[CrCl_2(H_2O)_4]+Cl'+OH'+H^{\cdot}$

$\rightleftharpoons[CrCl_2(H_2O)_4]OH+H^{\cdot}+Cl'$. The chlorine in the central group may also be displaced by an analogous process of ionization. At equilibrium, the conc. of the base will be directly proportional to the conc. of the OH′-ion, and consequently also with water in excess, inversely proportional to the conc. of the H˙-ion; and if this hydrolyzed product be the compound which passes into the violet form by a slow reaction, the colour change will be proportional to the conc. of the OH′-ion, and inversely as the conc. of the H˙-ion. Hence the retarding action of H˙-ions on the colour change, and precipitation. The acidity of the $[Cr(H_2O)_6]^{\cdots}$-ion was found by J. N. Brönsted and C. V. King to be governed by the ionization: $[Cr(H_2O)_6]^{\cdots}\rightleftharpoons H^{\cdot}+[Cr(OH)(H_2O)_5]^{\cdot\cdot}$, and the variation of the ionization constant, K, with the conc. is in agreement with $\log K=\log K_a-Z_b\sqrt{\mu}$, where μ is the ionic strength; K_a, the acid ionization constant; and Z, the valency of the ion.

N. Bjerrum measured the degree of hydrolysis of soln. of chromic chloride from potential of the hydrogen electrode in the cell $H_2 \mid CrCl_{3\,soln.},KCl_{sat.\,soln.} \mid 0{\cdot}1N$-calomel electrode. Assuming that $CrCl_3+H_2O=CrCl_2(OH)+HCl$, or more simply, $Cr^{\cdots}+H_2O=Cr(OH)^{\cdot\cdot}+H^{\cdot}$, the hydrolysis constant $K=[H^{\cdot}][Cr(OH)^{\cdot\cdot}]/[Cr^{\cdots}]$. At 25° it was found that for the soln. of the dark green salt K varied from $3{\cdot}25\times10^{-6}$ to $4{\cdot}3\times10^{-6}$, and it is less marked than is the case with the soln. of the violet salt —*vide infra*. J. Olie also obtained a similar conclusion with respect to hydrolysis by showing that iodine is more rapidly separated from a mixture of potassium iodide and iodate (5 : 1) by soln. of the violet salt than is the case with soln. of the green salt. A. B. Lamb and G. R. Fonda obtained for the hydrolysis constant $K=1{\cdot}8\times10^{-6}$ to $2{\cdot}0\times10^{-6}$ calculated from the conductivities of soln. in different proportions of hydrochloric acid, and from the rate of transformation: $[Cr(H_2O)_4Cl_2]Cl\rightarrow[Cr(H_2O)_6]Cl_3$. J. Sand and F. Grammling studied the gradual hydrolysis of the green salt by sodium hydroxide. Observations were also made by H. G. Denham, and G. van Pelt.

H. de Sénarmont heated an aq. soln. of chromic chloride in a sealed tube and obtained chromic oxide. According to H. Löwel, a soln. of the green chloride in three to five times its weight of water, develops hydrogen when treated with granulated zinc in the absence of air. A blue soln. of chromous chloride is formed. If the soln. be acidified, the zinc acts more quickly. The soln. slowly deposits the chromium as oxychloride. Iron does not reduce the chromic chloride, but it forms hydrogen and chromium oxychloride. If the soln. be boiled with tin, in the absence of air, hydrogen is developed but the soln. remains green, and on cooling crystals of tin chloride are deposited.

A. del Campo obtained **chromic triaquotrichloride,** $[CrCl_3(H_2O)_3]$, by the action of hydrogen chloride on a soln. of the green chloride, $[CrCl_2(H_2O)_4]Cl.H_2O$, at 90° to 100°, under press.

A. Hiendlmayr prepared **chromic fluopentamminodichloride,** $[Cr(NH_3)_5F]Cl_2$, by the action of hydrochloric acid on a soln. of the corresponding fluoride. An aq. soln. of the yellow, four-sided plates gives no precipitate with potassium ferricyanide, but if acetone be added there is a green precipitate; hydrofluosilicic acid gives no precipitate; and sodium picrate gives a yellow precipitate consisting of fine needles.

The blue, greyish-blue, or violet hexahydrate, $CrCl_3.6H_2O$.—This salt was obtained by A. Recoura by heating a 50 per cent. soln. of the dark green chloride for some minutes at 80°, and then treating it with hydrogen chloride at 0°, when crystals of the violet hexahydrate separate out. A. Werner and A. Gubser used a similar process, boiling the soln. for an hour before treatment with hydrogen chloride at 0°. H. W. B. Roozeboom and J. Olie said that the precipitation of the violet salt by passing hydrogen chloride into soln. of the green salt previously heated to 100° is possible, because at the latter temp. the green salt rapidly passes into the violet salt with which it assumes a state of equilibrium, and the reverse change is slow enough to allow the precipitation of the violet salt at a temp. where the green salt is the stable state. A. del Campo and co-workers obtained the hexa-aquochloride by the action of hydrogen chloride on a soln. of the violet sulphate at a low temp. G. O. Higley passed hydrogen chloride into a filtered soln. of 250 grms. of chrome alum in 1000 c.c. of conc. hydrochloric acid and 250 c.c. of water at 10°–15°. The crystals were dissolved in water and again precipitated with hydrogen chloride, and freed from the green isomer by washing with acetone. N. Bjerrum used the following process :

> Hydrogen chloride was passed into a soln. of 40 grms. of enneahydrated chromic nitrate in 40 grms. of water and 40 c.c. of 38 per cent. hydrochloric acid, cooled by running water. The precipitate was washed on asbestos with fuming hydrochloric acid, mixed with 30 c.c. of conc. hydrochloric acid and again precipitated with hydrogen chloride. The mother-liquor was decanted from the crystals. The crystals were then washed with acid-free acetone, and dried over sulphuric acid in vacuo. The yield was 24·5 grms.—theoretical 26·7 grms.

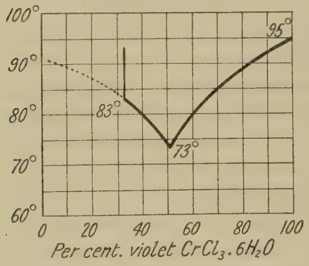

FIG. 76.—Melting-point Curve of the Dark Green and Violet $CrCl_3.6H_2O$.

Analyses in agreement with the formula $CrCl_3.6H_2O$ were made by A. Werner and A. Gubser, and R. F. Weinland and A. Koch—A. Recoura gave $CrCl_3.6\frac{1}{2}H_2O$. The colour of this form of chromic chloride ranges from grey to violet. According to J. Olie, they form six-sided, monoclinic prisms—R. F. Weinland and A. Koch added that lozenge-shaped plates are rare. W. Biltz and E. Birk gave 1·800 for the sp. gr. at 25°/4° ; and 148·1 for the mol. vol. J. Olie found the m.p. of the violet form to be 95°, and the m.p. curve of mixtures of the violet and dark green forms is shown in Fig. 76. The natural m.p.—**10**. 57, 5—of the green form is 83°, but that temp. really represents a mixture of the green form with 36 per cent. of the violet chloride. By extrapolation, the m.p. of the green chloride is over 90°. The salt can be slowly heated to 100° in vacuo without melting. Unlike the dark green salt, the violet chloride loses no water when confined over sulphuric acid at ordinary temp. S. Aoyama and co-workers studied the X-ray absorption and constitution. E. Feytis found the magnetic susceptibility to be $22·2 \times 10^{-6}$ mass unit ; and R. H. Weber made observations on this subject. A. Werner and A. Gubser found that the violet salt is more hygroscopic than the dark green salt ; it is easily soluble in water. As in the case of the dark green salt, the solubility, S per cent., of the violet chloride at 25° gradually increases with time owing to its passage into the green isomer. After a maximum of 72·22 per cent. has been attained, there follows a slow separation of the green salt (where the data are superscribed with an asterisk) :

Time .	$\frac{1}{6}$	4·5	24	48	96	120	216	288 hours.
S . .	61·99	63·19	63·88	66·16	70·68	72·22	68·95	70·01 per cent.
Violet .	98·47	96·70	91·54	83·37	69·11	62·20	54·63	46·39 ,,
Green .	1·53	3·30	8·46	16·63	30·89	37·80*	45·47*	53·61* ,,

A. Recoura gave 12·02 Cals. for the heat of soln. per mol ; and for the heat of formation $(CrCl_3.6H_2O)$=18·6 Cals. J. Olie estimated the heat of transformation from the dark green isomer to be −2·66 Cals. N. Bjerrum found that the violet salt passes into the green form particularly if moisture be present. J. Olie found the violet salt to be almost insoluble in absolute alcohol ; whereas A. Werner and A. Gubser said that it is easily soluble in alcohol, and insoluble in acetone. The behaviour of the salt on drying ; on treatment with silver nitrate ; and the conductivity of its aq. soln. are taken to be in agreement with the assumption that the violet salt is **chromic hexaquotrichloride,** $[Cr(H_2O)_6]Cl_3$, with no masked chlorine atoms. L. A. Welo gave $22·4 \times 10^{-6}$ mass units for the magnetic susceptibility.

Aq. soln. of the violet hexahydrate are violet ; and H. Löwel, and A. Recoura obtained the violet soln. by adding barium chloride to a soln. of the violet sulphate.

A. Recoura observed that if hydrated chromic oxide be precipitated from the green soln., and then dissolved in hydrochloric acid, a violet soln. is obtained. J. Olie obtained the violet soln. by adding alkali salts to the green soln., or by shaking the green soln. with barium carbonate, and dissolving the gelatinous hydrated chromic oxide in acids. J. Olie, and N. Bjerrum found that the velocity of transformation of the green into the violet soln. is favoured by a high degree of hydrolysis of the soln.; and A. B. Lamb observed that sodium acetate accelerated the transformation from green to violet soln., while A. Recoura, and L. Godefroy showed that acids retard the transformation, and N. Bjerrum found that nitrates favour the green chloride. V. V. Kuriloff observed that the transformation from green to violet soln. is favoured by exposure to light. There appears to be a state of equilibrium between the green and violet hexahydrates in aq. soln. which is slowly attained. Thus, at 25°, J. Olie found that with a green soln. of the percentage conc., *C*, the percentage proportions of the two hexahydrates in the soln. when equilibrium is attained, are

C .	3	19·70	22·72	34·70	50·19	57·57	68·50 per cent.
Violet .	100	93·1	95·1	87·1	68·7	60	42·5 ,,
Green .	0	6·9	4·9	12·9	31·3	40	57·5 ,,

The same state of equilibrium is attained if a violet soln. be used, for in that case the violet salt slowly passes into the green salt until equilibrium is attained. It will be observed that the more dilute the soln., the greater the corresponding proportion of violet salt for the equilibrium state. Raising the temp. results in an increase in the proportion of green salt. Thus, at 84°,

C . .	53·7	55·8	60·8	80·25 per cent.
Violet . .	68·10	48·51	48·15	37·35 ,,
Green . .	31·90	51·49	51·85	62·65 ,,

The speed of the transformation was measured by N. Bjerrum by measuring the change in the electrical conductivity or the change in the vol. of the soln.; and A. Heydweiller, by measuring the change in the conductivity, and in the sp. gr. of the soln. I. Koppel, and A. Werner and A. Gubser found that the velocity of transformation increases with the decreasing conc., and with increasing temp. Thus, with soln. containing a mol of chromic chloride in 125 litres of water, the molar conductivities μ mho, after the elapse of different periods of time, were

Time . .	0	2	6	10	22	32	375 mins.
μ . . .	110·9	134·8	166·1	181·3	211·9	225·4	307·4 mhos.

at 25°, and at 0°, changing the unit from minutes to hours,

Time .	0	0·5	6	18	24	73	88 hrs.
μ .	56·6	60·0	81·2	106·6	115·9	149·7	164·2 mhos.

and A. Heydweiller gave for soln. with 0·427 and 0·853 mols of the green salt per litre,

Time . .	0	7	12	20	40	61	153 min.
μ 0·427 .	42·75	57·81	62·33	65·60	67·53	67·67	— mhos.
0·853 .	—	79·85	84·3	89·0	96·0	98·0	99·7 ,,

N. Bjerrum found the results did not agree with the velocity equation for monomolecular reactions; but the results were better represented by velocity equations for two consecutive, bimolecular reactions, on the assumption that the reaction involves the sequence of changes: $[Cr(H_2O)_4Cl_2]Cl \rightarrow [Cr(H_2O)_5Cl]Cl_2 \rightarrow [Cr(H_2O)_6]Cl_3$. If *x*, *y*, *z* respectively denote the concentrations of these three salts, then $dx/dt=-k_1x$, and $dx/dt=k_2y$. It was found that at 25°, $k_1=0{\cdot}00272+0{\cdot}0000162/s$, and $k_2=(31/s+0{\cdot}005/s^2)10^{-7}$, where *s* denotes the conc. of free hydrochloric acid. For soln. with *M* mols of dark green chromic chloride, the percentage conversion, x, at the time t minutes, is as follows. With $M=0·008$ at 1° in aq. soln.,

Time . .	20	80	890	1490	4430	∞ mins.
x . .	2·5	8·3	38·8	32·9	80·1	100·0 mhos.

For $M=0·00322$ at 25° in aq. soln.,

Time . .	2	6	30	90	120	210 mins.
x . .	15·7	30·8	61·3	82·0	86·6	93·9 mhos.

For $M=0·01074$ at 25° in aq. soln.,

Time . .	3	9	30	90	180	∞ mins.
x . .	13·9	27·9	49·1	69·6	81·2	100·0 mhos.

The addition of chlorides displaces the equilibrium: $Cr(H_2O)_6^{\cdot\cdot\cdot}+3Cl' \rightleftharpoons [CrCl(H_2O)_5]^{\cdot\cdot}+2Cl'+H_2O \rightleftharpoons [CrCl_2(H_2O)_4]^{\cdot}+Cl'+2H_2O$, in accord with the law of mass action, namely, from left to right. For $M=0·01007$ at 25° in the presence of 0·0100N-NaCl,

Time . .	3	9	33	68	451	1564 mins.
x . .	13·9	27·9	51·4	65·2	94·0	99·9 mhos.

Similarly, hydrochloric acid favours the green chloride. For $M=0·00965$ at 25° in the presence of 0·01020N-HCl,

Time . .	20	60	100	290	2754	7140 mins.
x . .	3·8	11·4	18·0	38·4	76·7	94·5 mhos.

The effect of temp. is very pronounced—between 1° and 25°, k_1 increases 4·8 times per 10°, and k_2, 4 times. M. E. Baldwin also studied the effect of neutral chlorides on the transformation, and found that the hydrogen-ion conc. of chromium chloride soln. is increased by the presence of neutral chlorides, although the total amount of acid hydrogen remains constant. When the salts are arranged in order of increasing effect, the following series is obtained: (KCl, NH_4Cl), $NaCl$, $LiCl$, $BaCl_2$. I. Koppel found that in alcoholic soln., the transformation increases with dilution and with temp. With a mol of the salt in 214·36 litres of alcohol at 0°,

Time . .	12	18	24	42	95	∞ min.
x . .	5·71	7·15	8·32	10·99	14·79	16·80 mhos.

and with a mol of the salt in 273·9 litres of alcohol at 0°,

Time . .	10	30	81	141	231	∞ mins.
x . .	2·88	5·47	8·50	9·95	10·95	11·25 mhos.

N. Bjerrum found that there is a marked contraction in vol. as the green soln. passes into the violet soln.; a mol of the green salt per litre, at 25°, changes the sp. gr. of the soln. from 1·125 to 1·139 as it passes into the violet. The sp. gr. of soln. of the violet hexahydrate have not been directly determined, although some observations of A. Heydweiller gave approximate values—*vide infra*. For the effect of the violet salt on the critical soln. temp. of some binary mixtures, *vide supra*, the dark green salt. Expressing conc. by the number of grams of the salt, $CrCl_3.6H_2O$, in 100 grms. of water, G. Marchetti found for the lowering of the f.p.,

$CrCl_3.6H_2O$ . .	0·9698	2·2345	5·0046	8·1770	12·5039
F.p. . .	−0·240°	−0·0520°	−1·195°	−2·100°	−3·560°

and the calculated values for the mol. wt. range from 60·7 to 81·6. A. Werner and A. Gubser also obtained mol. wts. 74·8 to 79·1 from observations on the f.p. The theoretical value is 266·6, so that it is inferred that the ionization of the salt furnishes 4 ions. F. Jost obtained mol. wts. of 54·7 and 60·3 from the b.p. of soln. of the violet chloride in methyl alcohol. A. Recoura gave for the thermal value of the reaction $CrCl_{3\,\text{violet soln.}}+3NaOH_{\text{soln.}}=Cr(OH)_3+3NaCl+22·2$ Cals., and the precipitated hydroxide gives a blue soln. in hydrochloric acid and develops 20·7 Cals. The absorption spectrum of the soln. was discussed in connection with that of the dark green hydroxide, and there is a broad red absorption band in addition to the bluish-green band. N. Bjerrum gave for the molar electrical conductivity, μ mho, of aq. with M mols of salt per litre, at 25°,

M .	0·00097	0·00195	0·00390	0·00779	0·01559	0·03118
μ .	457·7	420·5	384·6	353·1	324·6	295·2

Measurements were also made by A. Werner and A. Gubser, A. Heydweiller, L. G. Winston and H. C. Jones, and E. J. Schaeffer and H. C. Jones. A. W. Speransky also found that the conductivity of the violet soln., at 25°, is $\mu_{25°}=324·5$ when that of the green soln. under similar conditions is $\mu_{25°}=126$. This is taken to prove that the violet salt furnishes more ions per mol than is the case with the green salt. F. Jost found for the conductivity of the violet salt in methyl alcohol,

M . . .	90·99	59·77	32·12	25·39	16·87
μ . . .	97·7	90·1	78·7	74·1	67·7 mhos.

K. Hopfgartner found the transport numbers for violet chromic chloride in 1·00, 0·32, and 0·075 eq. soln. to be respectively 0·318, 0·357, and 0·414, or extrapolating to zero concentration, 0·446. The mobilities of the ions are respectively 53, 49·5, and 46·3. These results indicate that the chromic ion is probably surrounded by a fairly large water sheath. N. Bjerrum found the constant of hydrolysis, as in the case of the dark green salt, and the percentage degree of hydrolysis, to be :

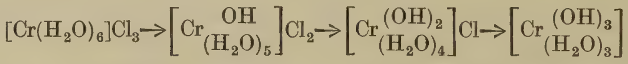
		0°	25°	50°	75°	100°
K . . .		0·000022	0·000098	0·00034	0·00103	0·00264
Hydrolysis	0·1M-	1·5	3·1	5·7	9·6	15·0 per cent.
	0·001M-	13·8	26·7	43·7	62·3	77·4 ,,

A. B. Lamb and G. R. Fonda gave $K=1·58\times10^{-4}$ at 25°. N. Bjerrum's value was $K=0·98\times10^{-4}$ at 25°. H. G. Denham, and G. van Pelt made observations on this subject, for the violet hexahydrate is intermediate between the value for aluminium chloride $K=0·14\times10^{-4}$, and the value for ferric chloride, 25×10^{-4}. Observations were made by J. N. Brönsted and K. Volqvartz. K. H. Gustavson found that the addition of progressive amounts of sodium chloride to soln. of chromic chloride causes an initial increase in the H˙-ion conc. represented by the value of p_H, and this is followed by a decrease with greater conc. of the sodium chloride. The latter effect is due to the increase in conc. of the chromium salt by hydration of the sodium chloride. The former change is most marked in dil. soln. of lesser acidity. It is supposed to be due to changes in the composition of the internal sphere in the chrome complex, different modifications of the basic aquo-chromic chlorides existing analogous to the normal chlorides $[Cr(H_2O)_6]Cl_3$, $[Cr(H_2O)_5Cl]Cl_2$, and $[Cr(H_2O)_4Cl_2]Cl$. The addition of sodium chloride will favour the formation of compounds with chlorine co-ordinately attached, and the increase in chlorine ions is evidenced by decrease in the electric charges of the cation and by an increase, in p_H. If sodium chloride is replaced by magnesium chloride, this effect is masked by the greater hydration tendency of the magnesium salt. The point at which precipitation occurs during addition of sodium hydroxide is not a function of p_H, but is proportional to the ratio of chlorine to chromium in the complex cation.

J. Sand and F. Grammling measured the velocity with which the violet hexahydrate liberates iodine from a mixture of potassium iodide and iodate, and found the results to be in agreement with the assumption that the molecule is $Cr_2Cl_6.12H_2O$, and not $[Cr(H_2O)_6]Cl_3$. H. W. Fischer found that the solubility of chromium hydroxide in an aq. soln. of green chromic chloride is not directly proportional to the conc. of the latter. A basic chloride is probably formed. From a soln. of chromium hydroxide in aq. chromic chloride, the former cannot be precipitated either by the addition of electrolytes or by the action of heat ; part of it is supposed to be in soln. in the colloidal form and part in the form of a compound containing chlorine. C. R. C. Tichborne said that, owing to hydrolysis, the green colour of the chromic salts is due to the formation of basic salts. The fact that the simplest way to convert the green soln. into a violet soln. is by boiling; that the change in colour of the green soln. is accompanied by the liberation of an acid, and the fact that incomplete precipitations with silver nitrate (and barium chloride) is a property common with elements known to be colloidal, led H. T. S. Britton to assume that the green soln. contain colloidal chromium hydroxide in which the cations of the colloidal electrolyte consist of chromium hydroxide associated with varying amounts of acid radicle. He showed that at 18°, 0·0133N-soln. of blue and green chromic chloride have respectively an e.m.f. of 0·467 and 0·409 volt against the N-calomel electrode; the $H^{\cdot}$-ion conc. are $p_H=3·19$ and 2·18; and the percentage hydrolysis 1·62 and 16·4. In the electrometric titration with sodium hydroxide, precipitation began when the e.m.f. were respectively 0·588 and 0·586 volt, when $p_H=5·28$ and 5·25; or when 1·07 and 1·43 eq. of NaOH per eq. of Cr had been added; and precipitation was complete when 2·78 and 2·15 eq. of alkali had been added. J. E. Howard and W. H. Patterson found that the effect of the violet and green salts on the critical soln. temp. of various mixtures is much greater than would be the case if the difference in the green and violet salts were due to the presence of basic, colloidal aggregates in the former. Colloids, *per se*, have usually a very small influence on the critical soln. temp. A. W. Ralston and J. A. Wilkinson found that soln. of the green and violet salts in liquid hydrogen sulphide are non-conducting.

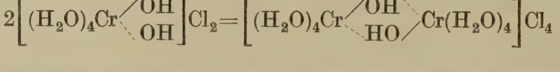
A. Recoura passed hydrogen chloride into a soln. of chromic chloride for some days. The soln. turns brown and then red, presumably because of the formation of a soluble complex $CrCl_3.nHCl$. On adding ether, this complex is precipitated in unstable green needles. R. Schwarz and G. Meyer found that while anhydrous chromic chloride does not take up hydrogen chloride readily, the violet hexahydrated chloride forms some complexes; and the green salt $[Cr(H_2O)_4Cl_2]Cl.2H_2O$ forms some complex chlorochromic acids at −50°, namely **tetrachlorochromic acid,** $CrCl_3.HCl.6·5H_2O$, **pentachlorochromic acid,** $CrCl_3.2HCl.8·5H_2O$, and **hexachlorochromic acid,** $CrCl_3.3HCl.10·5H_2O$, as dark green compounds which decompose when heated. J. R. Partington and S. K. Tweedy obtained impure tetrachlorochromic acid, $CrCl_3.HCl.6H_2O$, as a precipitate by slowly saturating at 0° a conc. soln. of dark green chromic chloride mixed with an equal vol. of ether. It is washed with dry ether.

The hydrolysis of chromic chloride formerly represented by $CrCl_3+H_2O \rightleftharpoons Cr(OH)Cl_2+HCl$; $Cr(OH)Cl_2+H_2O \rightleftharpoons Cr(OH)_2Cl+HCl$; and $Cr(OH)_2Cl+H_2O \rightleftharpoons Cr(OH)_3+HCl$, is now represented by A. Werner, and P. Pfeiffer as involving the formation of hydroxyl-compounds in the stages:



$$[Cr(H_2O)_6]Cl_3 \rightarrow \left[Cr\begin{matrix}OH\\(H_2O)_5\end{matrix}\right]Cl_2 \rightarrow \left[Cr\begin{matrix}(OH)_2\\(H_2O)_4\end{matrix}\right]Cl \rightarrow \left[Cr\begin{matrix}(OH)_3\\(H_2O)_3\end{matrix}\right]$$

With increasing hydrolysis, the $H^{\cdot}$-ion conc. of the soln. also increases. According to N. Bjerrum, with ageing, or more rapidly with heating, the hydroxyl compounds suffer an internal change producing the so-called *ol-salts*, which in contact with acids, are more stable than the hydroxyl salts. The action is represented graphically:

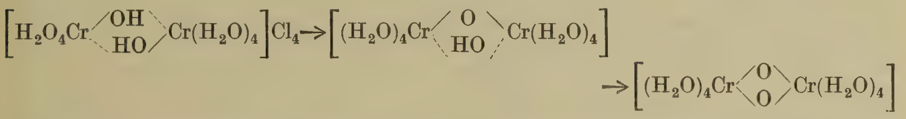


$$2\left[(H_2O)_4Cr\begin{matrix}OH\\OH\end{matrix}\right]Cl_2=\left[(H_2O)_4Cr\begin{matrix}OH\\HO\end{matrix}Cr(H_2O)_4\right]Cl_4$$

so that the molecular vol. of the salt in soln. increases and may assume the character of the colloid. When an acid is added to a hydroxyl compound some is consumed in reversing the change to form an aquo-compound $[Cr-OH]+HCl=[Cr...H_2O]Cl$, but with an ol-salt the first addition of acid simply increases the acidity of the soln., and thereafter gradually reforms the hydroxyl salt which then passes into the aquo-salt:

$$\left[(H_2O)_4Cr\left\langle\begin{matrix}OH\\HO\end{matrix}\right\rangle Cr(H_2O)_4\right]Cl_4\rightarrow 2\left[(H_2O)_4Cr\left\langle\begin{matrix}OH\\HO\end{matrix}\right.\right]Cl_2\rightarrow 2\left[Cr(H_2O)_6\right]Cl_3$$

The resistance offered by the different chromium complex salts to this change depends on the nature of the complex radicles—chloride, sulphate, formate, oxalate, etc. With longer ageing, or heating, a more drastic, irreversible, internal change occurs, which, according to D. Balanyi, results in the formation of oxy-salts, a change which makes the mother-liquor more acidic, thus:



$$\left[H_2O_4Cr\left\langle\begin{matrix}OH\\HO\end{matrix}\right\rangle Cr(H_2O)_4\right]Cl_4\rightarrow\left[(H_2O)_4Cr\left\langle\begin{matrix}O\\HO\end{matrix}\right\rangle Cr(H_2O)_4\right]\rightarrow\left[(H_2O)_4Cr\left\langle\begin{matrix}O\\O\end{matrix}\right\rangle Cr(H_2O)_4\right]$$

The resulting product is not attacked by standing in contact with cold dil. hydrochloric acid.

E. Stiasny and O. Grimm found that the properties of chromic chloride soln. depend largely on whether the liquor is heated before being rendered basic, on the degree of basicity, on the heating or ageing after being rendered basic, and on ageing after heating. When a basic chromium chloride soln. is boiled for 5 mins. the p_H value alters and only recovers after three days. It also decreases on ageing until it reaches 2·79 after four weeks; the addition of hydrochloric acid postpones the "ageing" effect. Heating before rendering the soln. basic causes chlorine to enter the chromium complex, but there is no chlorine in the complex after the soln. has been rendered basic and aged for a short time. The boiling of the soln. before rendering it basic encourages the formation of "ol" compounds; "ageing" has the same effect. Boiling is more effective in the formation of "ol" compounds and oxygen bridges after the liquor has been made basic than before. Heating increases the precipitation value both of normal and basic chromic chloride soln. owing to the formation of "ol" compounds which are less easily precipitable than the hydroxy-compounds. The heating effect is more pronounced with the more basic salts. Ageing diminishes the precipitation value of heated soln. of normal chloride which have not been heated, and of soln. of the basic salt which have been heated before and after rendering basic, but increases the value for basic soln. which have been boiled before rendering basic only. The dialytic properties of the different types of chromium chloride soln. are almost the same, showing that conversion into "ol" compounds does not result in the formation of large molecules unless the basicity exceeds 33 per cent. T. Murayasu found that the electrical conductivity of the soln. of chromic chloride is increased by adding glycocoll.

§ 23. The Chromium Oxychlorides

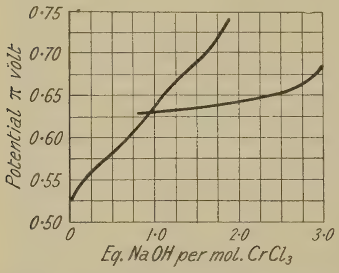

FIG. 77.—Electrometric Titration of Solutions of Chromic Chloride with Sodium Hydroxide.

The hydrolysis of chromic chloride, and the formation of some basic chlorides have just been discussed. N. Bjerrum[1] studied the titration of soln. of chromic chloride with sodium hydroxide, and calculated the $H^{\cdot}$-ion conc. from the potential measurements. The results with $0{\cdot}1M$-$CrCl_3$ and increasing proportions of $0{\cdot}1275M$-NaOH, at 17°, are illustrated by Fig. 77. When there is less than a mol of sodium hydroxide per mol of chromic chloride, the curve is steep, and the soln. remains clear; as soon as a mol of NaOH has been added, chromic hydroxide separates, and the soln. becomes turbid, and thereafter the $H^{\cdot}$-ion conc. increases slowly. So long as the soln. remains clear, the reaction is taken to be $Cr^{\cdots}+HOH=Cr(OH)^{\cdot\cdot}+H^{\cdot}$ for which the equilibrium constant $K_1=[Cr(OH)^{\cdot\cdot}][H^{\cdot}]/[Cr^{\cdots}]$, thereafter the reaction $Cr(OH)^{\cdot\cdot}+HOH=Cr(OH)_2{}^{\cdot}+H^{\cdot}$ sets in, and for this, $K_2[Cr(OH)_2{}^{\cdot}][H^{\cdot}]/[Cr(OH)^{\cdot\cdot}]$; and later on there is the reaction $Cr(OH)^{\cdot\cdot}+2H_2O=Cr(OH)_3+2H^{\cdot}$, for which $K_3=[H^{\cdot}]^2/[Cr(OH)^{\cdot\cdot}]$. He found for the hydrolysis constants of the green salt at 25°, $3{\cdot}8\times10^{-6}$; and of the blue salt at 0°, 17°, and 25°, $K_1\times10^4=0{\cdot}22$, 0·62, and 0·98 respectively; at 0° and 17°, $K_2\times10^4=0{\cdot}0025$ and 0·0059 respectively; and $K_3\times10^4=0{\cdot}278$ and 0·98 respectively. It is hence calculated that for $0{\cdot}01M$-$CrCl_3$ with the addition of x mols of $0{\cdot}1275N$-NaOH, the soln. contains the following proportions of the hydroxychlorides:

x . .	0	0·215	0·553	1·00	1·51	2·19	2·96
$CrCl_3$.	92·5	75·2	42·9	9·8	6·6	2·4	0
$Cr(OH)Cl_2$	7·5	22·9	52·3	74·9	57·3	29·2	1·2
$Cr(OH)_2Cl$	0	0·1	0·6	5·5	4·8	3·5	0·7
$Cr(OH)_3$.	0	0	0	2·4	20·5	50·0	78·9

It is also possible to calculate for the thermal values of these products $Cr(OH)Cl_2+HCl_{aq.}=CrCl_{3aq.}+H_2O+9600$ cals.; $Cr(OH)_2Cl+HCl_{aq.}=Cr(OH)Cl_2+H_2O+8060$ cals.; and $Cr(OH)_3+2HCl_{aq.}=Cr(OH)Cl_2+2H_2O+11{,}600$ cals. From the first and third equation, $Cr(OH)_3+3HCl_{aq.}=CrCl_{3aq.}+3H_2O+21{,}200$ cals., when A. Recoura found 20,700 cals. N. Bjerrum also added that it is probable that some polymerized basic chlorides exist. Observations on the electrometric titration of the chromic chlorides were also made by J. Sand and F. Grammling, who inferred from the potential of a hydrogen electrode, and the rate of liberation of iodine from an iodide-iodate mixture that the hydrolysis of the blue salt involves the breaking down of a doubled molecule: $Cr_2(H_2O)_{12}^{\cdot\cdot\cdot\cdot\cdot\cdot}+2H_2O\rightleftharpoons 2Cr(H_2O)_6OH^{\cdot\cdot}+2H^{\cdot}$, but N. Bjerrum did not agree. H. G. Denham obtained a value for the hydrolysis constant of the blue salt twice as great as N. Bjerrum. H. T. S. Britton found that with 0·0133*N*-soln. 1·62 per cent. of the violet, and 16·4 per cent. of the green salt was hydrolyzed at 18°. A. B. Lamb and G. R. Fonda calculated the hydrolysis constant of the green salt from conductivity data to be $1{\cdot}8\times10^{-6}$, and from the kinetics of the transformation $2{\cdot}0\times10^{-6}$. The hydrolysis constant for the violet salt calculated from the change of conductivity with conc. is $1{\cdot}52\times10^{-4}$; from the rate of transformation of the green salt, $1{\cdot}65\times10^{-4}$; from the rate of inversion of cane-sugar, $1{\cdot}60\times10^{-4}$; from the conductivity with or without the addition of hydrochloric acid, $1{\cdot}47\times10^{-4}$, and with the addition of sodium acetate, $1{\cdot}68\times10^{-4}$—mean value $1{\cdot}58\times10^{-4}$.

A number of basic chlorides have been reported by A. J. Béchamp and others, but their chemical individuality has not been established. A. Moberg, for example, said that $Cr_2O_3.8CrCl_3.24H_2O$ is formed by heating hydrated chromic chloride to 120°; H. Schiff regarded it as *chromic hydroxypentachloride*, $Cr_2Cl_5(OH).4H_2O$. By heating the hydrated salt to 150°, A. Moberg obtained $Cr_2O_3.4CrCl_3.9H_2O$, which H. Schiff regarded as *chromic dihydroxytetrachloride*, $Cr_2Cl_4(OH)_2.2H_2O$, or *chromium oxytetrachloride*, $Cr_2O.Cl_4.3H_2O$; E. M. Péligot obtained the same salt by heating the hydrated chloride to 200°, digesting the product with water, and drying it at 200°. H. Löwel obtained a similar product. B. Cabrera and S. P. de Rubies obtained the salt in green and violet modifications and studied their magnetic properties. V. Kletzinsky said that *chromic oxydichloride*, $Cr_4(OCl_2)_3$, is formed by evaporating to dryness a soln. of potassium chlorochromate in conc. hydrochloric acid. A. Moberg obtained *chromic oxychloride*, $Cr_2O_3.CrCl_3$, or $CrOCl$, by heating the hydrated chloride to dull redness. H. Schiff obtained the hydrate, $Cr_2O_3.CrCl_3.3H_2O$, or $CrCl(OH)_2$, *chromic dihydroxychloride*, by evaporating a soln. of chromic hydroxide in chromic chloride; and E. M. Péligot obtained a similar product from a mixture of a soln. of chromic chloride and alkali hydroxide. J. M. Ordway treated 6 mols of chromic hydroxide with 2 mols of hydrochloric acid and obtained $5Cr_2O_3.2CrCl_3$, which H. Schiff regarded as *chromic heptahydroxychloride*, $Cr_2(OH)_5Cl$. It was also obtained from a mixture of ammonia and a soln. of chromic chloride. A. Besson and L. Fournier heated a mixture of chromium trioxide and silicon hydrotrichloride in a sealed tube at 100°, and obtained a brown mass of *chromium oxyheptachloride*, Cr_3OCl_7. There are also N. Bjerrum's *chromic hydroxypentaquodichloride*, $[Cr(H_2O)_5(OH)]Cl_2$, and his *chromic dihydroxytetraquochloride*, $[Cr(H_2O)_4(OH)_2]Cl$, previously discussed.

R. F. Weinland and W. Friedrich[2] obtained what they called *pyridinium tetrachlorohydroxychromate*, $C_5H_5N.CrCl_4.OH,H_2O$, by the action of conc. hydrochloric acid and pyridine on chromic acid. The salt forms reddish-brown leaflets or orange-yellow, hexagonal plates. The analogous *quinolinium* compound was prepared. The interesting feature about these salts is that the chromium behaves as if it were quinquevalent, and the parent oxychloride is **chromium oxytetrachloride,** $CrOCl_3$. By saturating glacial acetic acid with hydrogen chloride, adding chromium trioxide, and then a soln. of alkali chloride in acetic acid soln., R. F. Weinland and M. Fiederer obtained **potassium chromium oxypentachloride,** $CrOCl_3.2KCl$, in dark garnet-red, rhombic prisms. The oxidizing power of the salt gradually diminishes when it is kept in a desiccator. The corresponding **rubidium chromium oxypentachloride,** $CrOCl_3.2RbCl$; **cæsium chromium oxypentachloride,** $CrOCl_3.2NH_4Cl$, are similarly prepared. The crystalline forms are similar to those of the corresponding salts of columbium and molybdenum. The cæsium salt is isomorphous with $CrOCl_3.2CsCl$. It was supposed that these products are salts of quinquevalent chromium, and a similar remark applies to various analogous compounds prepared by F. Olsson—*e.g.* $N(CH_3)_4CrOCl_4$; $N(C_2H_2)CrOCl_4$; etc.

J. J. Berzelius[3] discovered **chromium dioxydichloride,** or **chromyl chloride,** CrO_2Cl_2, which he obtained by distillation from a mixture of a chromate, sodium chloride, and conc. sulphuric acid. He thought that it was a higher chloride of chromium, but H. Rose proved that it contained oxygen. It was also analyzed by T. Thomson, P. Walter, and T. E. Thorpe, and these results, as well as the vap. density determinations of J. B. A. Dumas, P. Walter, E. Moles and L. Gomez, and E. Carstenjen; the f.p. determinations—*vide infra*—of R. E. Meyer and H. Best, and E. Moles and L. Gomez; and the b.p. determinations of E. Moles and L. Gomez, and G. Oddo and E. Serra are in agreement with the formula just indicated. The chromium is assumed to be sexivalent. E. R. Darling compiled a bibliography on the chemistry of chromyl chloride. G. Mazzaron said that the chlorides of silver, mercury, gold, and platinum, and antimony oxychloride give chlorine, not chromyl chloride when treated with potassium dichromate and sulphuric acid. F. Wöhler, A. Vogel, P. Walter, H. Rose, E. Burcker, E. Moles and L. Gomez, and G. Errera used modifications of this process: $3K_2CrO_4+6NaCl+12H_2SO_4=6KHSO_4+6NaHSO_4+3CrO_2Cl_2+6H_2O$. J. B. A. Dumas used lead chromate; potassium dichromate was used by T. Thomson. T. Thomson said that a better yield is obtained by using fuming sulphuric acid: $K_2Cr_2O_7+4NaCl+3H_2S_2O_7=2CrO_2Cl_2+K_2SO_4+2Na_2SO_4+3H_2SO_4$—but, added A. Étard, if the fuming acid be in excess, the chromyl chloride suffers some decomposition: $6CrO_2Cl_2+3H_2S_2O_7=2Cr_2(SO_4)_3+2CrO_3+6Cl_2+3H_2O$. H. Rose, and J. B. A. Dumas said that so much chlorine may be evolved that if the receiver is very cold, the product may solidify. P. Walter, and E. Carstanjen purified the liquid by fractional distillation for a number of times whereby the chlorine is given off first, and then the chromyl chloride, while sulphuric acid remains in the retort. T. E. Thorpe purified the liquid by fractional distillation in a current of carbon dioxide; and E. Moles and L. Gomez repeatedly fractioned the product after agitation with mercury. According to the Permutit A. G., an acid chloride, like chlorosulphonic acid, reacts with chromic acid or a chromate in the presence of conc. sulphuric acid or other diluting agent which does not decompose chromyl chloride; the acid anhydride—sulphur trioxide when chlorosulphonic acid is used—is converted into an acid chloride by the introduction of hydrochloric acid, and then acts on fresh chromic acid.

K. Heumann and P. Köchlin, and H. Moissan obtained chromyl chloride by the action of hydrogen chloride on dry chromium trioxide. W. Autenrieth treated chromium trioxide with 35 to 40 per cent. hydrochloric acid, and obtained a 35 per cent. yield of chromyl chloride, the yield is reduced with more dilute acid until with 20 per cent. hydrogen chloride, only chlorine is given off. H. Moissan also replaced the chromium trioxide with alkali or alkaline earth chromates; and moist chlorine can be used in place of hydrogen chloride at a temp. of 150°. L. Henry passed hydrogen chloride into sulphuric acid with chromium trioxide in suspension; and R. J. Meyer and H. Best suspended the chromium trioxide in glacial acetic acid; while H. D. Law and F. M. Perkin heated a soln. of chromium trioxide, conc. sulphuric acid, and conc. hydrochloric acid. A. Geuther chlorinated the chromium trioxide by heating it with anhydrous ferric or chromic chloride: $2FeCl_3+3CrO_3=Fe_2O_3+3CrO_2Cl_2$; H. Schiff, by phosphorus pentachloride; H. Erdmann, by chloroform: $2CHCl_3+CrO_3+O_2=2COCl_2+H_2O+CrO_2Cl_2$; A. Michael and A. Murphy, by carbon tetrachloride in a sealed tube at 150°–175°; and H. S. Fry, by acetyl chloride on a soln. of chromium trioxide in chloroform and acetic acid. A. Rosenstiehl treated chromates with pyrosulphuryl chloride; and K. Heumann and P. Köchlin used chlorosulphonic acid. E. M. Péligot treated potassium chlorochromate with sulphuric acid. H. Moissan found that moist chlorine attacks uncalcined chromic oxide at 440°, forming first chromic chloride which then reacts with the moisture forming chromyl chloride, and hydrogen chloride. The reaction is reversed at a higher temp. At 440°, also, oxygen acts on chromic chloride, forming chromyl chloride. P. Pascal found that chromyl chloride is formed by slowly heating pentachromyl hexachloride. F. G. Nunez prepared chromyl chloride of a high degree of purity for at. wt. determinations.

T. Thomson described chromyl chloride as a blood-red liquid which appears black by reflected light. G. J. Stoney and J. E. Reynolds found that chromyl chloride forms a yellowish-red vapour resembling nitrogen peroxide and E. Moles and L. Gomez observed that it freezes to form pale red, acicular crystals. T. Thomson gave 1·913 for the **specific gravity** of the liquid at 10°; P. Walter, 1·91 at 21°; T. E. Thorpe, 1·961 at 0°; 1·92 at 25°; and 1·7578 at the b.p. 115·9°; and E. Moles and L. Gomez, 2·0515 to 2·0528 at −47°/4°; 1·9582 to 1·9591 at 0°/4°; and 1·9113 to 1·9124 at 25°/4°. J. B. A. Dumas found the **vapour density** (air unity) to be 5·35 at 127° and 5·69 at 147°—when the theoretical value for CrO_2Cl_2 is 5·35; P. Walter found 5·9 at 143·7°; E. Carstanjen, 5·39 at 200°; and E. Moles and L. Gomez, 5·31 at 181°. Hence the vapour is not dissociated at these temp. T. E. Thorpe gave for the **thermal expansion** of unit vol. at 0° to v vols. at θ°, $v=1+0{\cdot}0_3958600\theta+0{\cdot}0_51073\theta^2+0{\cdot}0_81962\theta^3$. R. J. Meyer and H. Best found that the mol. wt., calculated from **the depression in the freezing point** of acetic acid, is 208 to 218—the theoretical value for CrO_2Cl_2 is 155. This shows that polymerization is taking place. E. Moles and L. Gomez found 175 to 189 with this solvent; 153 to 161 with phosphoryl chloride; 175·5 to 241 with nitrobenzene; 185 to 399 with ethylene dibromide; 91·8 to 97·8 with stannic bromide; and 193 to 215 with antimony pentachloride. Dil. soln. in nitrobenzene and ethylene dibromide show ionization, passing, with increasing concentration, into association. G. Oddo and A. Casalino found for 0·9694 and 2·4708 grms. of chromyl chloride in 100 grms. of the complex $SO_3.2POCl_3$ respectively 188 and 237 for the mol. wt.—theoretical 155. G. Oddo and E. Serra found from **the raising of the boiling point** of soln. in benzene, and carbon tetrachloride, mol. wts. between those required for the single and for the double molecule. E. Moles and L. Gomez obtained normal values when the results are corrected for the volatility of the solute—166·7 to 170·6 was obtained with carbon tetrachloride, and 164 to 172 with carbon disulphide. E. Beckmann gave 55·0 for the **ebulliscopic constant**—the mol. rise of the b.p.—of chromyl chloride when it is used as a solvent for mol. wt. determinations. E. Moles and L. Gomez gave −96·5° for the **melting point;** and for the **boiling point** P. Walter gave 118°; E. Carstanjen, 117·6° at 753 mm.; H. D. Law and F. M. Perkin, 118·5°–116°; T. E. Thorpe, 115·9° at 733 mm. and 116·8° at 760 mm.; and E. Moles and L. Gomez, 116·3° at 760 mm. The b.p., θ°, at different press., p mm., are:

p . .	232·3	338·0	424·0	525·0	645·8	750·8	763·1	839·1
B.p. .	79·4°	90·5°	97·4°	104·5°	111·0°	116·3	117·0°	120·4°

The data can be represented by $\theta=53{\cdot}63+0{\cdot}1271p-0{\cdot}000058p^2$. M. Berthelot found that the mol. **heat of soln.** in 100 parts of water at 8° is 16·67 Cals. The **absorption spectrum** of chromyl chloride was first examined by W. H. Miller, H. Mayer, B. Käbitz, R. Ritschl, and A. C. S. van Heel. G. J. Stoney and J. E. Reynolds found that the absorption spectrum shows orange yellow and green lines; they also observed that, excepting a small strip in the red, the vapour absorbs all the spectrum of a colourless flame. M. R. Read said that chromyl chloride imparts a pale white light to the colourless gas-flame; and F. Gottschalk and E. Drechsel added that if the vapour mixed with oxygen be passed into a non-luminous gas-flame, the colour is a paler violet than that imparted to the flame by potassium, and the flame spectrum shows three violet, eight green, one yellow, three orange-red, and two red lines. A. Cornu could not find any regularities in the spectral lines. According to B. Käbitz, liquid chromyl chloride absorbs the whole visible spectrum.

J. W. Hittorf, and E. Moles and L. Gomez found chromyl chloride to be a non-conductor of electricity. E. Moles and L. Gomez found that the mol. **electrical conductivity** is 5·05, 2·60, 1·38, and 0·96 mhos with soln. containing respectively 0·0323, 0·0724, 0·1398, and 0·2170 mol of CrO_2Cl_2 per litre of dried nitrobenzene at 25°. If the solvent is not thoroughly dried, the conductivity is two to five times as great, and it increases with time. The mol. conductivity decreases with increasing concentration, and the curves are parallel with those for the mol. wt. of chromyl chloride in the same solvent. P. Walden found the **dielectric constant** of the liquid to be 2·6 at 20°.

A. Étard said that chromyl chloride is very stable if it be protected from **light,** but in light it decomposes slowly forming chlorine and an oxide or oxychloride of chromium. F. Wöhler, and H. Quantin found that chromyl chloride is decomposed by **heat,** for when passed through a red-hot tube it furnishes crystals of chromic oxide: $2CrO_2Cl_2=Cr_2O_3+O+2Cl_2$; F. Wöhler, that a little above 300° it forms magnetic chromic chromate; and T. E. Thorpe, that at 180° to 190°, in a sealed tube, it forms chlorine and trichromyl chloride. If the vapour of chromyl chloride, mixed with dry **hydrogen,** be passed through a red-hot tube, A. Schafarik observed that it decomposes: $3CrO_2Cl_2+3H_2=6HCl+Cr_2O_3.CrO_3$; and when heated for a longer time, chromic oxide and oxygen are formed. F. Gottschalk and E. Drechsel said that a colourless gas-flame charged with a mixture of hydrogen and chromyl chloride becomes luminous, and deposits chromic oxide on a cold surface placed in the flame. J. B. A. Dumas, and P. Walter found that **water** decomposes chromyl chloride with the development of much heat forming a mixture of chromic and hydrochloric acids. J. J. Berzelius called the liquid *chlorwasserstoffsaure Chromsäure,* apparently regarding it as a special compound, for it was said to be formed by the action of hydrochloric acid on lead or silver chromate at the ordinary temp. The liquid is said to dissolve gold, and H. Moser found that when warmed chlorine is evolved. A. Étard, and J. B. A. Dumas observed that chromyl chloride absorbs **chlorine** freely, and becomes almost solid; H. W. B. Roozeboom found that the proportion of chlorine absorbed is dependent on the press. and temp. It increases rapidly as the temp. falls to —26° so that at 760 mm. press., a sat. soln. contains at 0°, 0·70 gram-atoms; at —14°, 1·24; at —21°, 2·31; and at —26°, 3·00. At 0°, the press., p mm., of soln. with N-gram-atoms of chlorine is:

Cl . . .	1·70	1·40	1·30	1·20	1·04	0·91
p . . .	1302	1198	1150	1101	1016	923 mm.

P. Walter said that chromyl chloride dissolves **iodine** without being decomposed; and R. W. E. McIvor said that when the mixture is distilled, iodine monochloride and trichromyl chloride are formed. H. Quantin found that dry **hydrogen chloride** reacts with chromyl chloride at a red-heat forming water, chlorine, and chromic oxide. J. B. A. Dumas found that **sulphur** decomposes chromyl chloride with a hissing noise; K. T. Kemp, and W. Gregory observed that a rose-coloured powder separates possibly chromic chloride; and T. Thomson added that when flowers of sulphur is moistened with it, the mixture ignites and burns with a red flame. K. T. Kemp found that if **hydrogen sulphide** be passed into chromyl chloride, the vessel becomes hot, hydrogen chloride is evolved, and a green powder is formed which A. Vogel said is probably chromic oxide. K. T. Kemp also found that if chromyl chloride vapour be passed through a narrow jet into the vapour of **sulphur monochloride,** vivid combustion occurs, and a rose-coloured powder is formed. K. Heumann and P. Köchlin observed that **chlorosulphonic acid** decomposes chromyl chloride; and, as indicated above, a similar remark applies to **pyrosulphuric acid.**

According to T. Thomson, chromyl chloride in **ammonia** solidifies with brilliant incandescence to form a dark brown mass, and with a more prolonged action on the residue, A. Schrötter, and C. E. Ufer found that chromium nitride or a mixture of nitride and oxide is formed. J. Heintze observed that with ammonia largely diluted by air, the residue, after washing, consists of chromic oxide. S. Rideal represented the reaction with dry ammonia, $3CrO_2Cl_2+8NH_3=6NH_4Cl+N_2+Cr_2O_3.CrO_3$. V. Thomas found that with **nitric oxide** and chromyl chloride vapour, a brown mass of **chromic dinitroxylheptoxypentachloride,** $Cr_5Cl_5O_7.2NO_2$, is formed; P. Pascal prepared pentitahexachloride by the action of nitric oxide—*vide infra.* J. B. A. Dumas, and P. Walter found that chromyl chloride explodes with **phosphorus,** and light is emitted at the same time—the effect is produced by a drop of the liquid and a piece of phosphorus the size of a pin's head. T. Thomson said that the phosphorus must be moistened to produce the explosion; when dry it is without action, and the flame of phosphorus is extinguished in the vapour of chromyl chloride. A. Michaelis observed that each drop of chromyl chloride added to well-cooled **phosphorus trichloride** produces a hissing noise, incandescence, and sometimes an explosion: $4CrO_2Cl_2+6PCl_3=4CrCl_3+3POCl_3+PCl_5+P_2O_5$. H. Schiff represented the reaction with **phosphorus pentachloride**: $2CrO_2Cl_2+4PCl_5=4POCl_3+3Cl_2+2CrCl_3$, and R. Weber, and A. W. Cronander added that some **chromium phosphoctochloride,** $CrCl_3.PCl_5$, is formed. H. S. Fry and J. L. Donnelly obtained the complex chromyl phosphoheptachloride, $CrO_2Cl_2.PCl_5$, by the action of chromyl chloride on a dry carbon tetrachloride soln. of phosphorus pentachloride. W. T. Casselmann showed that **phosphoryl chloride** reacts in the cold with chromyl chloride forming a black substance which decomposes at 100° as symbolized by $10POCl_3+12CrO_2Cl_2=18Cl_2+5P_2O_5+3Cr_2O_3+6CrCl_3$. E. Moles and L. Gomez found that chromyl chloride is soluble in phosphoryl chloride. H. S. Fry and J. L. Donnelly found that in soln. of dry carbon tetrachloride phosphorus trichloride reacts: $2CrO_2Cl_2+3PCl_3=PCl_5+2CrOCl.POCl_3$, and the deliquescent **chromium trioxyphosphotetrachloride** reacts with water: $CrOCl.POCl_3+2H_2O=CrCl_3+HCl+H_3PO_4$. On ignition, the complex **chromium trioxytrichloride,** CrOCl, or $Cr_2O_3.CrCl_3$ is formed. With **phosphorus tribromide, chromium trioxyphosphodichlorotribromide,** $2CrOCl.POBr_3$, is formed: $2CrO_2Cl_2+3PBr_3=2CrOCl.POBr_3+PBr_3Cl_2$. With **phosphorus pentabromide,** the complex **chromyl phosphodichloropentabromide,** $CrO_2Cl_2.PBr_5$, and **chromium dioxyphosphochlorotribromide,** $CrOCl.POBr_3$, are produced; with **phosphorus triiodide,** the complex **chromyl phosphodichlorotriiodide,** $CrO_2Cl_2.PI_3$, is formed, and it is decomposed by water: $2(CrO_2Cl_2.PI_3)+4H_2O=4HCl+4HI+I_2+2CrPO_4$; and with **phosphorus diodide,** the complex **chromyl phosphodichloridiiodide,** $CrO_2Cl_2.PI_2$ is formed: E. Moles and L. Gomez found that chromyl chloride is soluble in **antimony pentachloride,** and in **stannic bromide.**

J. B. A. Dumas, and T. Thomson found that **carbon** has no action on chromyl chloride. J. R. Mourelo and A. G. Banus found that the dried vapour of chromyl chloride mixed with air does not react: $4CrO_2Cl_2+4C+O_2=2Cr_2O_3+4COCl_2$, but chromic oxide is formed in the hot part of the tube and chromic chloride is deposited in the cooler part. It is difficult to get the charcoal free from hydrocarbons. The reaction of a mixture of chlorine and chromyl chloride with red-hot carbon is symbolized: $2CrO_2Cl_2+Cl_2+4C=2CrCl_3+4CO$. Chromyl chloride in general acts as an oxidizing and chlorinating agent on organic compounds: and in many cases the reaction is violent or explosive. H. Quantin found that when a mixture of the vapour of **carbon monoxide** and chromyl chloride is passed through a red-hot tube, chromic oxide and chloride are formed; and if the carbon monoxide be mixed with chlorine, and the temp. be 500° to 600°, carbon dioxide and chromic chloride are formed. P. Pascal obtained chromyl pentitahexachloride by reduction with carbon monoxide—*vide infra.* H. Erdmann, A. Emmerling and B. von Lengyel, and H. Quantin symbolized the reaction with **carbon tetrachloride**: $2CrO_2Cl_2+4CCl_4=2CrCl_3+4COCl_2+3Cl_2$. At ordinary temp. G. Oddo and E. Serra, and E. Moles and L. Gomez found it to be soluble in carbon tetrachloride; and R. J. Meyer and H. Best added that there is no action with carbon tetrachloride; and J. B. A. Dumas, none with **carbon disulphide,** and E. Moles and L. Gomez found that chromyl chloride dissolves in this liquid; and A. Étard found that in a sealed tube carbon disulphide reacts forming a complex mixture of products; and under similar conditions chloroform, with chromic acid and oxygen, furnishes carbonyl chloride, hydrogen chloride, and chromyl chloride; H. Erdmann, and A. Emmerling and B. von Lengyel represented the reaction: $2CHCl_3+CrO_3+O_2=2COCl_2+CrO_2Cl_2+H_2O$. F. Wöhler, and K. T. Kemp found that **ethylene** reacts forming ethylene chloride. E. Moles and L. Gomez found that it is soluble in **ethylene dibromide,** and in **nitrobenzene.** T. Thomson said that **turpentine** is inflamed by chromyl chloride, while **wood-spirit, camphor,** and **olive oil** are decomposed ; F. Wöhler found that **indigo** is not acted upon. F. Wöhler, P. Walter, and T. Thomson observed that with absolute **alcohol,** enough heat is generally evolved to produce combustion, and may be an explosion with violent projection of the liquids. R. J. Meyer and H. Best found that alcohol, **ether,** and **acetone** react with incandescence ; **benzene** is slowly attacked, but **toluene,** *o*-**xylene, pyridine,** and **quinoline** are vigorously attacked. A. Étard studied the reaction with **acetic acid** in a sealed tube at 100°, and obtained $Cr_2O_7\{Cr_2(C_2H_3O_2)_5\}_2.8H_2O$. E. Moles and L. Gomez studied soln. in acetic acid. The **aliphatic hydrocarbons,** $R.CH_3$, form the corresponding aldehyde, R.CO.H, with the formation of the intermediate compounds :

$$R.CH\begin{matrix}\diagup O.Cr(OH)Cl_2\\ \diagdown O.Cr(OH)Cl_2\end{matrix}\rightarrow R.CH\begin{matrix}\diagup O.CrO.Cl\\ \diagdown O.CrO.Cl\end{matrix}\rightarrow R.CO.H$$

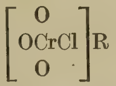
The reactions with aliphatic hydrocarbons, and various other organic compounds were studied by A. Étard, V. von Richter, P. Friedländer, E. Carstanjen, G. G. Henderson and co-workers, A. Haller, J. Bredt and W. Jagelki, D. Spence and J. C. Galletly, etc. Many of these reactions are discussed by G. Rohde, *Das Chromylchlorid und die Étard'sche Reaktion* (Stuttgart, 1901). J. B. A. Dumas, and P. Walter found that **mercury** is violently attacked by chromyl chloride.

According to E. Zettnow,[4] when chromyl chloride is distilled from a mixture of potassium chlorochromate and sulphuric acid, there is also formed a brown mass which is separated from the chromyl chloride, dissolved in water, and dried. Its composition corresponds with **chromyl tritadichloride,** $(CrO_2)_3Cl_2$. R. J. Meyer and H. Best represented it by the formula $Cl.CrO.O.CrO_2.O.CrO.Cl$. T. E. Thorpe made it by heating chromyl chloride in a sealed tube at 180° to 190° : $3CrO_2Cl_2=Cr_3O_6Cl_2+2Cl_2$; and R. W. E. McIvor, by distilling the iodine monochloride from a soln. of iodine in chromyl chloride : $3CrO_2Cl_2+2I_2=4ICl+Cr_2O_2Cl_2$. P. Pascal made it by heating chromyl pentitahexachloride. The black amorphous compound, said T. E. Thorpe, is reduced to chromic oxide when heated to a low temp. in hydrogen ; and R. W. E. McIvor obtained chromic oxide by heating it in air. According to T. E. Thorpe, and R. W. E. McIvor, when exposed to air the tritadichloride deliquesces to a reddish-brown syrup which smells of chlorine ; it is freely soluble in water forming a dark brown liquid which gives off chlorine ; a nitric acid soln. behaves as if it contained hypochlorous acid ; with hydrochloric acid, it forms a dark brown soln. which, when heated, gives off chlorine and forms chromic chloride ; with ammonia it forms ammonium chloride and chromate, and chromic chromate ; and, according to S. G. Rawson, it is scarcely soluble in carbon disulphide, but forms red soln. with alcohol, and ether.

According to P. Pascal, **chromyl pentitahexachloride,** $(CrO_2)_5Cl_6$, is formed when nitric oxide is passed into chromyl chloride, cooled in a bath of water ; heat is evolved and a crystalline paste is formed, nitrosyl chloride is evolved : $5CrO_2Cl_2+4NO=4NOCl+(CrO_2)_5Cl_6$, when the excess of chromyl chloride is removed, in vacuo at 100°, there remains the pentitahexachloride as a brown crystalline powder of sp. gr. 2·51. Carbon monoxide in sunlight can effect the same reduction as nitric oxide. Unlike chromyl chloride, the pentitahexachloride is strongly magnetic so that the function of chromium in the chromyl, CrO_2-radicle, and in the $(CrO_2)_5$-radicle appears to be different. In fact, chlorine, which acts only above 150°, slowly converts the pentitahexachloride back to chromyl chloride. Chromyl pentitahexachloride is deliquescent, and readily dissolves in water to a dark brown soln. with an odour of chlorine and the reactions of chromium salts, chromic acid, and hydrochloric acid. If slowly heated to 150°, chromyl chloride is evolved, and if quickly heated, chlorine only, the solid product in both cases being the tritadichloride, $(CrO_2)_3Cl_2$. Above 180° oxygen is evolved, leaving an insoluble brownish-black residue of $Cr_6O_9Cl_4$. Towards hydrogen, hydrogen sulphide, etc., chromyl subchloride acts as a chlorinating agent at low temp., whilst above 200° its action is generally an oxidizing as well as a chlorinating one. Moist gaseous ammonia acts very violently, the products being ammonium chloride, oxygen, and the oxides CrO_2 and Cr_2O_3. Generally speaking, however, chromyl pentitahexachloride is less reactive than chromyl chloride. When chromyl pentitahexachloride is suspended in dry ether, and a current of slightly moist ammonia is passed through, nitrogen is evolved, and ammonium chloride and a brown, amorphous precipitate remain. Ammonium chromate and chromium chromate are removed from the precipitate by washing, and the pale brown, insoluble residue when dried at 90° has the composition of an explosive *ammonium chromite*, $(NH_4O)_6(CrO_2)_5$.

According to G. Herfeldt,[5] if eq. proportions of chromium trioxide and chromyl chloride are heated in a sealed tube at 180°, impure **chlorochromic oxide,** $Cr_2O_5Cl_2$, or $(CrO_2Cl)_2O$, is formed. It is suggested that it is the anhydride, $CrO_2Cl–O–CrO_2Cl$, of the hypothetical *chlorochromic acid,* $HCrO_3Cl$, or $HO.CrO_2Cl$. The pale red compound is said to be very reactive, for it reacts explosively with alcohol, pyridine, and quinoline. A number of salts, **chlorochromates,** has been prepared. E. M. Péligot, and S. Löwenthal prepared **ammonium chlorochromate,** $(NH_4)CrO_3Cl$, as in the case of the potassium salt. It has the same appearance, but is much more soluble. S. Löwenthal prepared **lithium chlorochromate,** $LiCrO_3Cl$, from an aq. soln. of chromyl chloride and lithium chromate mixed with acetic acid. The yellowish-red crystals are, according to A. Fock, monoclinic; they are easily fused to a reddish-brown liquid; and are freely soluble in water. E. M. Péligot obtained **sodium chlorochromate,** $NaCrO_3Cl.2H_2O$, by adding sodium chloride to a conc. aq. soln. of chromyl chloride; G. Prätorius, by adding chromyl chloride to a conc. soln. of sodium carbonate in chromic acid, and allowing the mixture to stand some days in a desiccator over conc. sulphuric acid; and A. Ditte, by adding sodium chloride to a soln. of chromic acid. The dark reddish-yellow, prismatic crystals, when dried by press. between porous tiles lose water, and form an amorphous, yellow mass. If kept in a badly closed vessel, water of crystallization is taken up again. The compound melts by the heat of the hand, and at 110° loses chlorine, and water.

E. M. Péligot obtained **potassium chlorochromate,** $KCrO_3Cl$, by boiling potassium dichromate for a short time with an excess of hydrochloric acid, and cooling the liquid: $K_2Cr_2O_7+2HCl=H_2O+2KCrO_3Cl$—if boiled for too long a time some chromic acid is reduced; he also obtained it by mixing equimolar parts of potassium chloride and chromic acid in aq. soln., and adding hydrochloric acid—G. Herfeldt used a similar process. E. M. Péligot, and A. Werner, treated chromyl chloride with a sat. soln. of potassium chloride: $CrO_2Cl_2+KCl+H_2O=2HCl+KCrO_3Cl$; A. Ditte added potassium chloride to a hot soln. of an eq. quantity of chromic acid; A. Michaelis, by the action of phosphorus trichloride on potassium dichromate; A. Geuther added chromyl chloride to soln. of potassium chromate in dil. acetic acid: $K_2CrO_4+CrCl_2O_2=2KCrO_3Cl$; and also violet chromic chloride to molten potassium dichromate, $3K_2Cr_2O_7+2CrCl_3=Cr_2O_3+6KCrO_3Cl$. If the temp. is too high, chlorine may be given off. If the cold mass be dissolved in water acidified with acetic acid, and evaporated, the excess of potassium dichromate first separates out, and then follows the potassium chlorochromate. L. Varenne discussed the constitution of these salts, which are usually represented $RO.CrO_2.Cl$, or according to A. Werner's scheme:



$$\left[\begin{matrix}\mathrm{O}\\ \mathrm{OCrCl}\\ \mathrm{O}\end{matrix}\right]\mathrm{R}$$

E. M. Péligot said that the salt forms rectangular prisms, the colour of potassium dichromate; and that the salt is stable in air; A. Ditte found that the salt furnishes yellow needles which darken in air; and R. J. Meyer and H. Best, that when crystallized from acetic acid soln. over sulphuric acid, the salt is stable. G. N. Wyrouboff gave for the axial ratios of the monoclinic prisms $a:b:c=0·9653:1:1·0174$, and $\beta=90°\ 20'$. L. Playfair and J. P. Joule gave 2·49702 for the sp. gr. at 39°. J. Heintze, and J. G. Gentele said that when heated to 100°, the salt gives off chlorine; G. Herfeldt observed no evolution of chlorine below 250°, and he said that even after heating at 500° to 600° for some hours about 8 per cent. of chlorine remains in the residue. A. Streng also found that some oxygen is given off. A. Schafarik found that the salt readily fuses to a dark brown liquid with the evolution of chlorine and the formation of chromic oxide. A. C. Oudemans represented the reaction: $4KCrO_3Cl = K_2Cr_2O_7 + Cr_2O_3 + 2KCl + Cl_2 + O_2$; and A. Ditte noticed that a little chromyl chloride is also formed. F. Morges made some observations on the electrolysis of soln. of the salt. A. Ditte said that the salt is not decomposed when dissolved in water; and F. Morges gave 4·65 Cals. for the heat of soln. in 488 mols of water. E. M. Péligot found that the evaporation of the aq. soln. of the salt gives potassium dichromate; but with dil. hydrochloric acid the salt does not decompose; with conc. hydrochloric acid, potassium chloride, chromic chloride, and chlorine are formed. A. Ditte also noticed the evolution of chlorine when the salt is treated with hydrochloric acid. V. Kletzinsky observed that a violet mixture of potassium chloride and basic chromic chloride, $Cr_2O_3.2CrCl_3$—or possibly potassium chromium chloride, $KCrCl_4$—is formed by evaporating the soln. in conc. hydrochloric acid. E. M. Péligot found that with conc. sulphuric acid, chromyl chloride is evolved. H. Schiff gave for the reaction with fused potassium sulphate: $K_2SO_4 + KCrO_3Cl = KCl + KO.SO_2.O.CrO_2.OK$; and with potassium hydrosulphate; $KHSO_4 + KCrO_3Cl = HCl + KO.SO_2.O.CrO_2.OK$. J. Heintze observed that with ammonia, ammonium chloride, potassium chromochromate, etc., are formed, while A. Leist said that the products are potassium and ammonium dichromates, ammonium chloride, and chromic oxide. If the salt under ether, freed from moisture and alcohol, be treated with dry ammonia, chromium amidochromate is formed. A. Naumann found the salt to be soluble in acetone. J. Heintze said that the salt does not act on ether or benzene, but it oxidizes alcohol, and aniline; and a hot conc. soln. of potassium cyanide forms cyanogen chloride and potassium chromate.

E. M. Péligot reported **calcium chlorochromate,** $Ca(CrO_3Cl)_2.5H_2O$, to be formed as in the case of the potassium salt; but G. Prätorius could obtain it only by mixing 10 grms. of calcium carbonate or acetate with the theoretical quantity of solid chromium trioxide, forming 30 c.c. of acetic acid—containing an equal part of water and chromic acid—over the mixture and adding the calculated quantity of chromyl chloride. The reddish-yellow liquid is warmed on a water-bath, and the salt crystallizes out on cooling. The yellow, deliquescent salt melts in its water of crystallization at 56°. G. Prätorius obtained **strontium chlorochromate,** $Sr(CrO_3Cl)_2.4H_2O$, from an acetic acid soln. of strontium chromate, chromium trioxide and chromyl chloride. The carmine-red crystals melt without decomposition at 72°; they lose water when confined over sulphuric acid; and they form an orange liquid with water. Only impure, orange-yellow crystals of **barium chlorochromate** were prepared by G. Prätorius from glacial acetic acid soln. of barium chromate and chromyl chloride; but he obtained from the soln. a complex with acetic acid, **barium tetracetochlorochromate,** $Ba(CrO_3Cl)_2.4CH_3COOH.2H_2O$. He also obtained yellow crystals of **barium chlorochromatochloride,** $Ba(CrO_3Cl)Cl$, probably rhombic, from the mother-liquor remaining after the separation of the preceding salt, treated with conc. acetic acid on a water-bath. The hygroscopic crystals are freely soluble in water, and the yellow soln. when warmed deposits barium chromate; when the salt is heated, chromyl chloride is evolved. If the mother-liquor just indicated be acidified with dil. hydrochloric acid, yellow, six-sided plates of the *hydrate,* $Ba(CrO_3Cl)Cl.H_2O$, are formed. E. M. Péligot, and S. Löwenthal prepared **magnesium chlorochromate,** $Mg(CrO_3Cl)_2.9H_2O$, as in the case of the potassium salt, and G. Prätorius, from a soln. of magnesium carbonate in an excess of chromic acid and dil. hydrochloric acid. The reddish-yellow, hygroscopic, rhombic crystals melt in their water of crystallization at 66°; they form the *pentahydrate* when confined over sulphuric acid; and they lose chlorine and water at 135° to 140°. The salt is freely soluble in water. G. Prätorius prepared **zinc chlorochromate,** $Zn(CrO_3Cl)_2.9H_2O$, as in the case of the magnesium salt; and S. Löwenthal, from a cold, conc. soln. of zinc chloride and chromic acid acidified with acetic acid, and he dried the crystals on porous tiles. The reddish-yellow, hygroscopic, prismatic or tabular crystals decompose over sulphuric acid in a desiccator, giving off chlorine; they melt in their water of crystallization at 37·5°; they lose some water and chlorine at 100°. Chlorine is evolved when the salt is treated with lead oxide. M. Lachaud and C. Lepierre prepared impure **thallous chlorochromate,** $TlCrO_3Cl$, from a soln. of thallous chloride and chromic acid in a little water. The prismatic crystals are decomposed by water into thallous chloride and chromic acid. L. Bourgeois fused a mixture of lead chromate and chloride and obtained hexagonal prisms of **lead dichlorochromate,** $PbCl_2.PbCrO_4$. W. J. Sell prepared **chromic hexacarbamidochlorochromate,** $[Cr(CON_2H_4)_6](CrO_3Cl)_2.3H_2O$. G. Prätorius prepared hygroscopic, dark orange-yellow crystals of **cobalt chlorochromate,** $Co(CrO_3Cl)_2.9H_2O$, from a mixed soln. of chromic acid, cobalt carbonate and chromyl chloride. The crystals melt in their water of crystallization at 40° without decomposition; and they lose water on exposure to air. For **cobaltic hexamminochlorochromate,** $[Co(NH_3)_6]Cl(CrO_4).nH_2O$, *vide supra*, the chromates. The corresponding **nickel chlorochromate,** $Ni(CrO_3Cl)_2.9H_2O$, was obtained by G. Prätorius in a similar manner to the cobalt salt; the dark orange-yellow, hygroscopic crystals melt in their water of crystallization at 46° to 48°.

§ 24. The Chromium Ammines

The ammines of chromium were first obtained by E. Frémy [1] in 1858, and they were soon afterwards studied by P. T. Cleve, and then by J. Morland, A. Reinecke, and S. M. Jörgensen. A. Werner showed that as in the case of the cobalt, and platinum ammines, most of the chromium ammines fitted into the system based on his co-ordination theory—**8**. 49, 19. I. I. Chernyeff studied the inner structure of the chromium ammines. Extensive investigations on the chromium ammines have been made by P. Pfeiffer and his fellow-workers, and the following summary is based on his reports :

A.—Compounds with one chromium atom in the nucleus.

I.—**The hexammine family,** or compounds of the tervalent basic group : $[CrA_6]'''$.

(i) *Hexammines*, $[Cr(NH_3)_6]X_3$. These salts are the so-called *chromium luteosalts*, studied by S. M. Jörgensen, A. Benrath, O. T. Christensen, W. R. Lang and C. M. Carson, J. Meyer and L. Speich, H. J. S. King, P. Pfeiffer and S. Basci, L. A. Welo, and P. Pfeiffer and M. Haimann, J. Petersen, O. Stelling, O. Hassel and G. B. Næss, E. Wilke-Dörfurt and co-workers, and A. Werner and A. Miolati. These salts include : (1) chloride and (2) its mercurichloride, and (3) chloroplatinate ; (4) bromide and (5) its bromoplatinate ; (6) iodide, and (7*a*) its sulphate, and (7*b*) selenate; (8) perchlorate; (9) sulphate and (10) its chloroplatinate; (11) nitrate and (12) its chloroplatinate; (13) dinitratofluosulphonate; (14) phosphate and (15) its sodiopyrophosphate; (16) oxalate and (17) its chromioxalate, (18) its cobaltioxalate; (19) cyanide and (20) its chromicyanide, (21) its ferricyanide; (22) its cobalticyanide; (23) picrate; (24) dipicrylamide; (25) 2 : 4-dinitro-α-naphthoxide; (26) 2 : 4-dinitro-α-naphthoxide-γ-sulphonate; (27) 2 : 3 : 6-trinitrophenoxide; (28) 1 : 2-naphthaquinone-1-oximate (1-nitroso-β-naphthoxide); (29) 1 : 2-dihydroxyanthraquinone; (30) picramate, and (31) permanganate.

(ii) *Trisethylenediamines*, $[\mathrm{Cr\,en_3}]X_3$. These salts were studied by J. Meyer and L. Speich, L. A. Welo, P. Pfeiffer, P. Pfeiffer and A. Trieschmann, P. Pfeiffer and M. Haimann, and A. G. Berghman. They include: (1) chloride; (2) bromide; (3) iodide; (4) nitrate; (5) selenate; (6) oxalate, and (7) its chromioxalate, and (8) cobaltic oxalate; (9) cyanide, and (10) its chromicyanide, and (11) cobalticyanide; (12) thiocyanate, and (13) its chromithiocyanate; and (14) dichromate.

(iii) *Hexacarbamides*, or *hexaurea salts*, $[\mathrm{Cr(NH_2.CO.NH_2)_6}]X_3$. W. J. Sell, M. Kilpatrick, P. Pfeiffer, A. Werner and D. Kalkmann, G. A. Barbieri, and J. Meyer and L. Speich, E. Wilke-Dörfurt and co-workers studied these salts, and reported: (1) the chloride, and its complex (2) with mercuric chloride, and (3) with platinic chloride; (4) bromide; (5) perbromide; (6) iodide; (7) periodide; (8) chlorate; (9) perchlorate; (10) hexasulphide; (11) sulphate; (12) hydrosulphate; (13) chlorosulphate; (14) bromosulphate; (15) perbromosulphate; (16) iodosulphate; (17) periodosulphate; (18) chloratosulphate; (19) perchlorate; (20) perchloratosulphate; (21) persulphate; (22) fluosulphonate; (23) sulphatofluosulphonate; (24) thiosulphate; (25) selenate; (26) periodocarbonate; (27) nitrite; (28) sulphatonitrite; (29) cobaltinitrite; (30) diamminotetranitritocobaltiate; (31) chlorodiamminotetranitritocobaltiate; (32) nitrate; (33) sulphatonitrate; (34) cyanide; (35) thiocyanate; (36) ferrocyanide; (37) ferricyanide; (38) nitroprusside; (39) manganicyanide; (40) cobalticyanide; (41) chloronickelocyanide; (42) chloroplatinocyanide; (43) hexathiocyanatochromiate; (44) hexacyanochromiate; (45) fluosilicate; (46) fluoborate; (47) fluoboratosulphate; (48) chromate; (49) chlorochromate; (50) dichromate; (51) chlorodichromate; (52) bromodichromate; (53) perchloratodichromate; (54) disulphatodichromate; (55) nitratodichromate; (56) tetrafluoboratodichromate; (57) permanganate; (58) sulphatopermanganate; (59) dichromatopermanganate; (60) oxalate; (61) picrate; (62) naphthalene-2-sulphonate; (63) toluenesulphonate; (64) *o*-dichlorobenzenesulphonate; (65) sulphatobenzenesulphonate; and (66) diflavianate-flavianate. E. Wilke-Dörfurt and R. Pfau studied the isomorphism of the permanganate, perchlorate, fluoborate, fluosulphonate, and iodide.

(iv) *Bisethylenediaminopropylenediamines*, $[\mathrm{Cr\,en_2pn}]X_3$. These salts were studied by P. Pfeiffer, P. Pfeiffer and H. Pietsch, and P. Pfeiffer, T. Gassmann. They include: (1) bromide; (2) iodide; (3) oxalate and (4) its chromioxalate, and (5) cobaltioxalate; (6) cyanide, and its (7) chromicyanide, and (8) cobalticyanide; and (9) thiocyanate.

(v) *Trispropylenediamines*, $[\mathrm{Cr\,pn_3}]X_3$. These salts were studied by P. Pfeiffer and M. Haimann, and P. Pfeiffer and T. Gassmann. They include: (1) iodide; (2) cobaltioxalate; (3) chromicyanide; (4) cobalticyanide; (5) thiocyanate; and (6) chromithiocyanate.

(vi) *Aquopentammines*, $[\mathrm{Cr(NH_3)_5(H_2O)}]X_3$. These salts are the so-called *chromium roseo-salts,* studied by S. M. Jörgensen, F. Ephraim and W. Ritter, A. Benrath, O. Hassel and G. B. Næss, A. Hiendlmayr, and O. T. Christensen. They include: (1) hydroxide; (2) fluoride—*vide supra,* (3) chloride, and (4) its mercurichloride; (5) bromide, and (6) its bromoplatinate; (7) iodide; (8) perchlorate; (9) sulphate, and (10) its chloroplatinate; (11) nitrate, and (12) hydronitrate; (13) cyanide, and (14) its chromicyanide, (15) its ferricyanide, and (16) its cobalticyanide. H. J. S. King showed that these salts may be hydroxypentammines.

(vii) *Diaquotetrammines,* $[Cr(NH_3)_4(H_2O)_2]X_3$. These salts were investigated by P. Pfeiffer. They include: (1) hydronitrate; (2) chloride; and (3) bromide.

(viii) *Diaquobisethylenediamines,* $[Cr\,en_2(H_2O)_2]X_3$. These salts were studied by P. Pfeiffer. These are the isomeric forms:

(*a*) *Cis-salts,* including (1) chloride; (2) bromide; (3) chromioxalate; and (4) chromithiocyanate.

(*b*) *Trans-salts,* including (1) chloride; and (2) bromide.

(ix) *Triaquotriammines,* $[Cr(NH_3)_3(H_2O)_3]X_3$. These salts were studied by A. Werner, S. Guralsky, and E. H. Riesenfeld and F. Seemann and they include: (1) the chloride; (2) the perchlorate; (3) the bromide; (4) hydroxyiodide; and (5) chloronitrate.

(x) *Tetraquodiammines,* $[Cr(NH_3)_2(H_2O)_4]X_3$. These salts were studied by A. Werner and J. Klein. They include: (1) chloride; (2) bromide; (3) sulphate.

(xi) *Tetraquodipyridines,* $[Crpy_2(H_2O)_4]X_3$. These salts were studied by P. Pfeiffer, P. Pfeiffer and W. Osann, and P. Pfeiffer and M. Tapuach. They include: (1) chloride; (2) bromide; (3) sulphate, and (4) hydrosulphate; (5) nitrate; and (6) chromicyanide.

(xii) *Diaquotetramido-salts,* $[Cr(H_2O)_2(C_2H_5O_2N)_4]$, studied by G. Florence and E. Couture.

(xiii) *Hexaquo-salts,* $[Cr(H_2O)_6]X_3$. These salts were studied by A. Werner and A. Gubser, A. Gubser, A. Werner and R. Huber, P. Pfeiffer, R. F. Weinland and R. Krebs, R. F. Weinland and T. Schumann, and L. A. Welo. They correspond with the hexahydrated chlorides, sulphates, and chlorosulphates. J. Meyer and L. Speich prepared the selenate.

(xiv) *Hexa-antipyrino-salts,* $[Cr(COC_{10}H_{12}N_2)_6]X_3$, were prepared by E. Wilke-Dörfurt and H. G. Mureck. For example, (1) the fluoborate, $[Cr(COC_{10}H_{12}N_2)_6](BF_4)_3$; (2) the permanganate; (3) the fluosulphonate; (4) the thiocyanate; (5) the dichromate; (6) the chlorate; (7) the thiosulphate; (8) the ferrocyanide; (9) the ferricyanide; and (10) the picrate.

(xv) *Trioxalato-salts,* $R_3'[Cr(C_2O_4)_3]$, studied by A. G. Berghman.

II.—**The pentammine family,** or compounds of the bivalent, basic group: $[CrA_5X]''$. P. Larisch made some comparative observations on the solubilities of these salts.

(i) *Hydroxypentammines,* $[Cr(NH_3)_5(OH)]X_2$. S. M. Jörgensen, P. Pfeiffer, A. Werner, A. Benrath, L. A. Welo, J. V. Dubsky, and H. J. S. King reported (1) chloride; (2) bromide; (3) iodide; (4) sulphate; (5) dithionate; (6) nitrate; (7) chromate; (8) oxalate; (9) picramate; (10) picrate; (11) dipicrylamide; and (12) 2 : 4-dinitro-α-naphthoxide-γ-sulphonate. The (13) hydroxide was obtained by the action of silver oxide on the chloride.

(ii) *Hydroxyaquopentammines,* $[Cr(NH_3)_5(H_2O)(HO)]X_2$. These salts were studied by P. Pfeiffer. They include: (1) bromide; and (2) dithionate.

(iii) *Hydroxyaquobisethylenediamines*, $[Cr\ en_2(H_2O)(HO)]X_2$. These salts were studied by P. Pfeiffer, P. Pfeiffer and R. Stern, P. Pfeiffer and R. Prade, P. Pfeiffer and T. G. Lando. There are isomeric forms:

(*a*) *Cis-salts*, including (1) chloride; (2) bromide; (3) iodide; and (4) dithionate.

(*b*) *Trans-salts*, including (1) bromide; (2) iodide and (3) dithionate.

(iv) *Hydroxydiaquotriammines*, $[Cr(NH_3)_3(H_2O)_2(HO)]X_2$ The iodide was studied by A. Werner.

(v) *Hydroxytriaquodiammines*, $[Cr(NH_3)_2(H_2O)_3(OH)]X_2$. The sulphate was studied by A. Werner and J. Klein, and A. Werner and V. Dubsky.

(vi) *Hydroxytriaquodipyridines*, $[Crpy_2(H_2O)_3(OH)]X_2$. These salts were studied by P. Pfeiffer, P. Pfeiffer and M. Tapuach, and P. Pfeiffer and W. Osann. They include: (1) chloride; (2) sulphate; and (3) thiocyanate.

(vii) *Nitritopentammines*, $[Cr(NH_3)_5(NO_2)]X_2$. They are the so-called *chromium xantho-salts*. These salts were studied by O. T. Christensen, J. N. Brönsted and A. Petersen, and A. Werner and A. Miolati. They include: (1) chloride, and (2) its mercurichloride, and (3) its chloroplatinate; (4) bromide; (5) iodide; (6) sulphate; (7) dithionate; (8) nitrate; (9) carbonate; (10) chromate; and (11) dichromate.

(viii) *Nitratopentammines*, $[Cr(NH_3)_5(NO_3)]X_2$. These salts were studied by A. Werner and J. von Halban. They include: (1) iodide and (2) nitrate.

(ix) *Nitratodiaquotriammines*, $[Cr(NH_3)_3(H_2O)_2(NO_3)]X_2$. The nitrate was studied by E. H. Riesenfeld and F. Seemann.

(x) *Fluopentammines*, $[Cr(NH_3)_5F]X_2$. These salts were prepared by A. Hiendlmayr. They include: (1) fluoride; (2) chloride; (3) nitrate; (4) chromate; and (5) ferricyanide.

(xi) *Chloropentammines*, $[Cr(NH_3)_5Cl]X_2$. These are the so-called *chromium purpureo-salts*. They were studied by O. T. Christensen, A. Werner and A. Miolati, O. Hassel and G. B. Næss, F. Ephraim and W. Ritter, J. Meyer and L. Speich, J. N. Brönsted and A. Petersen, H. J. S. King, L. A. Welo, and S. M. Jörgensen. They include: (1) chloride; (2) its mercurichloride, and (3) its chloroplatinate; (4) bromide, and (5) its mercuribromide; (6) iodide, and (7) its mercuriiodide; (8) chlorate; (9) perchlorate; (10) pentasulphide; (11) sulphate, and (12*a*) its hydrosulphate; (12*b*) selenate; (13) dithionate; (14) fluosilicate; (15) oxalate; (16) ferrocyanide; (17) chromate; (18) picrate; (19) 2 : 4-dinitro-α-naphthoxide; (20) 2 : 4-dinitro-α-naphthoxide-γ-sulphonate; and (21) 2 : 3 : 6-trinitrophenoxide.

(xii) *Chloroaquotetrammines*, $[Cr(NH_3)_4(H_2O)Cl]X_2$. These are the so-called *chromium roseo-salts*. They were studied by E. Frémy, P. T. Cleve, A. Werner and A. Miolati, S. M. Jörgensen, J. Petersen, P. Pfeiffer and S. Basci, P. Pfeiffer. They include: (1) chloride, and its (2) mercurichloride, and (3) its chloroplatinate; (4) bromide; (5) iodide; (6) sulphate; (7) nitrate; (8) fluosilicate; (9) oxalate; and (10) chromate.

(xiii) *Chlorodiaquotriammines*, $[Cr(NH_3)_3(H_2O)_2Cl]X_2$. These salts were studied by E. H. Riesenfeld and F. Seemann. They include: (1) chloride; and (2) sulphate.

(xiv) *Bromodiaquotriammines*, $[Cr(NH_3)_3(H_2O)_2Br]X_2$. These salts, prepared by S. Guralsky, include: (1) chloride; (2) bromide; and (3) sulphate.

(xv) *Chloropentaquo-salts*, $[Cr(H_2O)_5Cl]X_2$. These salts have been discussed in connection with the hydrates of chromic chlorides. They were discussed by N. Bjerrum, A. Recoura, R. F. Weinland and R. Krebs, and R. F. Weinland and T. Schumann. The series is represented by (1) chloride; (2) sulphate; and (3) chlorosulphate. J. Meyer and L. Speich made (4) the selenate.

(xvi) *Bromopentammines*, $[Cr(NH_3)_5Br]X_2$. These salts were studied by S. M. Jörgensen, and A. Werner and A. Miolati. They are represented by (1) chloride; (2) bromide, and (3) its bromoplatinate; (4) nitrate; and (5) chromate.

(xvii) *Bromoaquotetrammines*, $[Cr(NH_3)_4(H_2O)Br]X_2$. The salts were studied by P. T. Cleve, and P. Pfeiffer and S. Basci. They include: (1) chloride; (2) bromide; and (3) sulphate.

(xviii) *Bromoaquobisethylenediamines*, $[Cr\,en_2(H_2O)Br]X_2$. The salts were studied by P. Pfeiffer, P. Pfeiffer and R. Stern, and P. Pfeiffer and T. G. Lando. They include: (1) bromide; and (2) chromithiocyanate.

(xix) *Bromodiaquotriammines*, $[Cr(NH_3)_3(H_2O)_2Br]X_2$. A. Werner prepared (1) the chloride; (2) the bromide; and (3) the sulphate.

(xx) *Iodopentammines*, $[Cr(NH_3)_5I]X_2$. These salts were studied by A. Werner and A. Miolati, and S. M. Jörgensen. The salts include: (1) chloride, and (2) its chloroplatinate; (3) iodide; and (4) nitrate.

(xxi) *Iodoaquotetrammines*, $[Cr(NH_3)_4(H_2O)I]X_2$. P. T. Cleve prepared the iodide.

(xxii) *Thiocyanatopentammines*, $[Cr(NH_3)_5(SCy)]X_2$. The salts were studied by A. Werner and J. von Halban. The salts include: (1) chloride; (2) bromide; (3) nitrate; (4) thiocyanate; and (5) dichromate.

(xxiii) *Sulphatopentaquo-salts*, $[Cr(H_2O)_5(SO_4)]X_2$. The chloride was prepared by R. F. Weinland and T. Schumann.

III.—**The tetrammine family,** or compounds of the univalent basic group: $[CrA_4X'X']$. P. Larisch made some comparative observations on the solubilities of these salts.

(i) *Dihydroxydiaquodiammines*, $[Cr(NH_3)_2(H_2O)_2(OH)_2]X$. These salts were prepared by A. Werner and J. V. Dubsky, and A. Werner and J. L. Klein. The salts include: (1) chloride; (2) bromide; (3) iodide; (4) dithionate; and (5) thiocyanate.

(ii) *Dihydroxydiaquodipyridines*, $[Crpy_2(H_2O)_2(HO)_2]X$. These salts were prepared by P. Pfeiffer, P. Pfeiffer and W. Osann, and P. Pfeiffer and M. Tapuach. The salts include: (1) chloride; (2) bromide; (3) iodide; (4) sulphate; (5) nitrate; and (6) thiocyanate.

(iii) *Dichlorotetraquo-salts*, $[Cr(H_2O)_4Cl_2]X$, represented by J. Meyer and L. Speich's $[Cr(H_2O)_4Cl_2](SeO_4)_2[Cr(H_2O)_6]$. The salts are represented by the (1) chloride and its complexes with (2) antimonic chloride, and (3) cæsium chloride; as well as by the (4) sulphate. They were studied by A. Werner and A. Gubser, N. Bjerrum, R. F. Weinland and K. Feige, O. Stelling, and P. Pfeiffer.

(iv) *Dihydroxydiaquoethylenediamines*, $[Cr(H_2O)_2\,en(OH)_2]X$. These salts, prepared by E. Weinmann, include: (1) chloride; (2) perchlorate; (3) bromide; (4) iodide; (5) dithionate; and (6) thiocyanate.

(v) *Dichlorobisethylenediamines*, $[Cr\,en_2Cl_2]X$. These salts were studied by A. Werner, P. Pfeiffer, P. Pfeiffer and P. Koch, P. Pfeiffer and T. G. Lando, P. Pfeiffer and R. Stern, and P. Pfeiffer and A. Trieschmann. There are the isomeric forms:

(*a*) *Inactive salts*, including (1) chloride and (2) its antimonichloride, and (3) chloroplatinate; (4) bromide; (5) iodide; (6) sulphate; (7) dithionate; (8) nitrate; and (9) thiocyanate.

(*b*) *Dextro-cis salts*, including (1) chloride; (2) bromide, and (3) its bromocamphorsulphonate; and (4) nitrate.

(*c*) *Lævo-cis-salts*, including (1) chloride; (2) bromide, and (3) its bromocamphorsulphonate; and (4) nitrate.

(*d*) *Trans-salts*, including (1) chloride, and (2) its hydrochloride, and (3) chloroplatinate; (4) bromide; (5) iodide; (6) dithionate; (7) nitrate; (8) chromidioxalatoethylenediamine; and (9) thiocyanate.

(vi) *Dichloroaquotriammines*, $[Cr(NH_3)_3(H_2O)Cl_2]X$. These salts were prepared by A. Werner, F. Frowein, E. H. Riesenfeld and F. Seemann, and S. Guralsky, and include: (1) chloride; (2) iodide; (3) sulphate; (4) hydrosulphate; and (5) nitrate.

(vii) *Dibromoaquotriammines*, $[Cr(NH_3)_3(H_2O)Br_2]X$. These salts, prepared by S. Guralsky, include: (1) bromide; (2) iodide; (3) sulphate; (4) nitrate; and (5) thiocyanate.

(viii) *Dichlorodiaquodiammines*, $[Cr(NH_3)_2(H_2O)_2Cl_2]X$. A. Werner and J. L. Klein prepared the chloride.

(ix) *Dichlorodiaquodipyridines*, $[Crpy_2(H_2O)_2Cl_2]X$. These salts were prepared by P. Pfeiffer and M. Tapuach, and include: (1) chloride, and (2) its complex with pyridinium chloride; (3) bromide; and (4) nitrate.

(x) *Dibromotetraquo-salts*, $[Cr(H_2O)_4Br_2]X$. These salts are represented by the chloride prepared by N. Bjerrum.

(xi) *Dibromobisethylenediamines*, $[Cr\,en_2Br_2)X$. They were studied by P. Pfeiffer, and P. Pfeiffer and A. Trieschmann. There are isomeric forms:

(*a*) *Cis-salts*, including (1) bromide; (2) iodide; and (3) dithionate.

(*b*) *Trans-salts*, including (1) bromide and (2) its hydrobromide, and (3) its mercuribromide; (4) iodide; (5) dithionate; (6) nitrate; and (7) thiocyanate.

(xii) *Dichloroaquotriammines*, $[Cr(NH_3)_3(H_2O)Cl_2]X$. The chloride was studied by E. H. Riesenfeld and F. Seemann.

(xiii) *Dibromodiaquodiammines*, $[Cr(NH_3)_2(H_2O)_2Br_2]X$. A. Werner and J. L. Klein, and A. Werner and J. V. Dubsky studied the bromide.

(xiv) *Dibromodiaquopyridines*, $[Cr(NH_3)_2(H_2O)_2Br_2]X$. These salts were studied by A. Werner and A. Gubser, and P. Pfeiffer and M. Tapuach. The salts include: (1) bromide; (2) iodide; and (3) nitrate.

(xv) *Dibromotetraquo-salts*, $[Cr(H_2O)_4Br_2]X$. These salts were studied by A. Recoura, A. Werner and A. Gubser, A. Werner and R. Huber, P. Pfeiffer and M. Tapuach, and N. Bjerrum. The salts include: (1) chloride; (2) bromide; (3) sulphate; and (4) the cobaltic tetranitritodiammine.

(xvi) *Diiodobisethylenediamines*, $[Cr\,en_2I_2]X$. The double salt with mercuric iodide was studied by P. Pfeiffer and T. G. Lando.

(xvii) *Dithiocyanatotetrammines*, $[Cr(NH_3)_4(SCy)_2]X$. These salts were studied by P. Pfeiffer and M. Tilgner, and A. Werner and J. von Halban. The salts include: (1) chloride; (2) bromide; (3) sulphate; (4) nitrate; and (5) thiocyanate.

(xviii) *Dithiocyanatobisethylenediamines*, $[Cr\,en_2(SCy)_2]X$. These salts were studied by P. Pfeiffer and M. Haimann, P. Pfeiffer and P. Koch, P. Pfeiffer and R. Stern, and P. Pfeiffer. There are isomeric forms:

(*a*) *Cis-salts*, including (1) chloride; (2) bromide; (3) iodide and its complex with mercuric iodide; (4) sulphate; (5) nitrate; (6) thiocyanate; and (7) chromithiocyanate.

(*b*) *Trans-salts*, including (1) chloride; (2) bromide, (3) sulphate; (4) nitrate; (5) thiocyanate; and (6) chromithiocyanate.

(xix) *Oxalatotetrammines,* $[Cr(NH_3)_4(C_2O_4)]X$. These salts were studied by P. Pfeiffer and S. Basci. The salts include: (1) chloride; (2) bromide; (3) iodide; (4) nitrate; and (5) chromidioxalatodiammine.

(xx) *Oxalatobisethylenediamines,* $[Cr\,en_2(C_2O_4)]X$. These salts were studied by P. Pfeiffer, P. Pfeiffer and R. Stern, and P. Pfeiffer and A. Trieschmann, and H. Schwarz. The salts include: (1) bromide; (2) iodide; (3) chromidioxalatoethylenediamine; and (4) the chromidioxalatodiaquo-salt. Some other oxalato-salts were studied by R. Weinland and W. Hübner, and F. Hans.

IV.—**The triammine family,** or compounds of the null-valent group: $[CrA_3X_3']$.

(i) *Trichlorotriammine,* $[Cr(NH_3)_3Cl_3]$, was prepared by A. Werner, E. H. Riesenfeld and F. Seemann, F. Frowein, O. Stelling, S. Guralsky, and H. I. Schlesinger and co-workers. There are also the tribromide and the mixed chlorobromides.

(ii) *Trihydroxyaquodiammines,* $[Cr(NH_3)_2(H_2O)(OH)_3]$. The *tetrahydrate* was studied by A. Werner and J. L. Klein.

(iii) *Trihydroxyaquodipyridines,* $[Crpy_2(H_2O)(OH)_3]$. The *hexahydrate* was studied by P. Pfeiffer and M. Tapuach.

(iv) *Dichlorohydroxyaquodipyridine,* $[Crpy_2(H_2O)Cl_2]$. This salt was prepared by P. Pfeiffer and M. Tapuach.

(v) *Trichlorotripyridine,* $[Crpy_3Cl_3]$. This salt was examined by P. Pfeiffer. The addition products with (1) $2CH_3Cy$, and (2) C_2H_5Cy were examined by P. Pfeiffer.

(vi) *Trichloroaquodipyridine,* $[Crpy_2(H_2O)Cl_3]$. This salt was studied by P. Pfeiffer and M. Tapuach.

(vii) *Triaquotrichlorides,* $[Cr(H_2O)_3Cl_3]$. The addition product with 2Py.HCl was studied by P. Pfeiffer.

(viii) *Trisethylalcoholotrichloride,* $[Cr(C_2H_5.OH)_3Cl_3]$. This compound was examined by I. Koppel.

(ix) *Trichlorotrithiourea,* $[Cr(CSN_2H_4)_3Cl_3]$. *The hemihydrate* was examined by P. Pfeiffer.

(x) *Triaquotribromides,* $[Cr(H_2O)_3Br_3]$. The addition product with 2PyHBr was studied by P. Pfeiffer.

(xi) *Trithiocyanatotriammine,* $[Cr(NH_3)_3(SCy)_3]$. This compound was studied by A. Werner and J. von Halban.

(xii) *Trithiocyanatoaquodiammines,* $[Cr(NH_3)_2(H_2O)(SCy)_3]$. The monohydrate was studied by O. Nordenskjöld, J. A. Siemssen, and A. Werner and G. Richter; (1) the addition product with (2) ethylenediammine, (3) piperidine; (4) aniline, (5) brucine; and (6) pyridine were studied by O. Nordenskjöld, and J. A. Siemssen.

(xiii) *Dichlorothiocyanatotriammine,* $[Cr(NH_3)_3(SCy)Cl_2]$. This salt was prepared by S. Guralsky.

V.—**The diammine family,** or compounds of the univalent, acidic group: $[CrA_2X_4]$.

(i) *Tetrathiocyanatodiammines,* $[Cr(NH_3)_2(SCy)_4]M$. These compounds were studied by J. Morland, A. Reinecke, P. T. Cleve, O. Nordenskjöld, R. Escales and H. Ehrensperger, J. A. Siemssen, E. Orloff, O. T. Christensen, A. Werner and G. Richter, A. Werner and J. L. Klein, and P. Pfeiffer and M. Tilgner. The compounds include: (1) the acid and its monohydrate or dihyrate; (2) sodium; (3) potassium—*Reinecke's salt*—and (4) its complex with potassium iodide; (5) rubidium, and (6) a complex with pyridine; (7) cæsium, and (8) a complex with pyridine; (9) copper; (10) barium; (11) zinc, (12) a complex with pyridine; and (13) one with ammonia; (14) cadmium; (15) mercury; (16) iron; (17) cobalt; (18) ammonium and (19) its hydrate, and (20) iodide; (21) nitrosyl; (22) guanidine; (23) methylamine; (24) dimethylamine; (25) trimethylamine;

(26) ethylamine; (27) amylamine; (28) tetramethylammonium; (29) methylpyridinium; (30) methylquinolinium; (31) *m*-xylidinium; (32) ethylenediamine; (33) pentamethylenediamine; (34) aniline; (35) ammonium aniline; (36) *o*-toluidine; (37) *p*-toluidine; (38) phenylhydrazine; (39) piperidine; (40) pyridine; (41) picoline; (42) quinoline; (43) morphine; (44) quinine; (45) strychnine; (46) pilocarpine; and (47) cocaine.

(ii) *Tetrathiocyanatodipyridines*, $[CrPy_2(SCy)_4]M$. These compounds were studied by J. Sand and O. K. H. Burger, and P. Pfeiffer and W. Osann. The salts include: (1) potassium—the dihydrate, and tetrapyridine; (2) sodium—the trihydrate, and tetrapyridine; and (3) the mono- and di-pyridines.

(iii) *Tetrathiocyanatoethylenediamine*, $[Cr\,en(SCy)_4]M$. These compounds, prepared by E. Weinmann, include: (1) sodium; (2) potassium; (3) cæsium; (4) ammonium; (5) caffeine; (6) coniine; (7) nicotine; (8) narcotine; (9) codeïne; (10) strychnine; and (11) brucine.

(iv) *Dioxalatodiammines*, $[Cr(NH_3)_2(C_2O_4)_2]M$. P. T. Cleve, and P. Pfeiffer and S. Basci studied the complex which the group forms with chromic oxalatotetrammine.

(v) *Dioxalatoethylenediamines*, $[Cr\,en(C_2O_4)_2]M$. These salts were studied by H. Schwarz, P. Pfeiffer, P. Pfeiffer and A. Trieschmann, P. Pfeiffer and R. Stern, and P. Pfeiffer and R. Prade. The salts include: (1) potassium and its complex with potassium iodide; (2) the addition product with chromic *trans*-dichlorobisethylenediamine; (3) the addition product with chromic oxalatobisethylenediamine; (4) the addition product with cobaltic dichlorobisethylenediamine, and its dihydrate.

(vi) *Dioxalatodiaquo-salts*, $[Cr(H_2O)_2(C_2O_4)_2]M$. The (1) ammonium; (2) sodium; and (3) potassium salts were studied by A. Rosenheim and L. Cohn, and P. Pfeiffer and R. Stern.

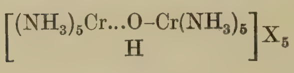
VI.—**The monammine family,** or compounds of the bivalent, acidic group: $[CrAX_5]$. These compounds are represented by the pentahalides—*vide supra*—studied by A. Werner, and A. Werner and A. Gubser—*e.g.*, (1) $M_2[Cr(H_2O)F_5]$; (2) $M_2[Cr(H_2O)Cl_5]$; and (3) $M_2[Cr(H_2O)Br_5]$.

VII.—**The hexa-acid family** or compounds of the tervalent, acidic group: $[CrX_6]$. These compounds are represented by (1) $M_3[CrF_6]$; (2) $M_3[CrCy_6]$; (3) $M_3[Cr(SCy)_6]$; and (4) $M_3[Cr(C_2O_4)_3]$, studied by H. Schwarz, L. A. Welo, P. Pfeiffer, and J. A. Siemssen.

B.—Polychromic compounds, that is, compounds with more than one chromium atom in the nucleus.

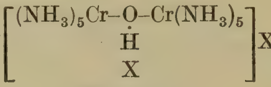
I.—**Dichromic salts**—with two chromium atoms in the nucleus. Some salts prepared by P. Schützenberger in 1868—*viz.* $[Cr_2O(CH_3COO)_3(NO_3)]$; $[Cr_2(CH_3COO)_4(NO_3)(OH)]$; and $[Cr_2(CH_3COO)_5.NO_3]$ may belong to this group. There are also salts of the type $[Cr_2(OH)(OOC.CH_2SCy)_4]X$, described by R. G. Krasnowskaja including the hydroxide, chloride, bromide, iodide, sulphate, and dithionate; and D. R. Camhi's $[Cr_2(OOC.CH_2Cy)_6OH]X$.

(i) *Hydroxydecammines*, $[Cr_2(OH)(NH_3)_{10}]X_5$. These salts were studied by S. M. Jörgensen, A. Werner, J. Petersen, and P. Pfeiffer. S. M. Jörgensen called them the *chromium rhodo-salts*; and A. Werner, *decammine-ol-dichromic salts*. The rhodo-salts include: (1) chloride, (2) its chloraurate, and (3) its chloroplatinate; (4) bromide, and (5) its bromoplatinate; (6) iodide; (7) sulphate; (8) dithionate; and (9) nitrate. These salts have a neutral reaction; and A. Werner represented them by the following formula in order to show their relationship with the isomeric erythro-salts—*vide infra*—which have an acidic reaction :



$$\left[(NH_3)_5Cr\ldots\underset{H}{O}-Cr(NH_3)_5\right]X_5$$

Rhodo-salts.



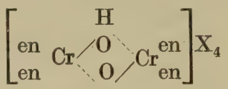
$$\left[(NH_3)_5Cr-\underset{\underset{X}{H}}{O}-Cr(NH_3)_5\right]X_4$$

Erythro-salts.

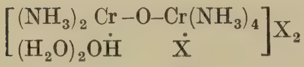
There are the so-called *basic rhodo-salts,* $[Cr_2(OH)(NH_3)_{10}]X_4(OH)$, studied by S. M. Jörgensen, and A. Werner. They are represented by (1) chloroiodide ; (2) bromide ; and (3) dithionate. The rhodo-salts are isomeric with the *erythro-salts* studied by S. M. Jörgensen, and represented by (1) chloroiodide ; (2) chloroplatinate ; (3) bromide ; (4) sulphate ; and (5) nitrate.

(ii) *Oxydecammines,* $[Cr_2O(NH_3)_{10}]X_4$, or $[(NH_3)_3Cr-O-Cr(NH_3)_5]X_4$. They were studied by S. M. Jörgensen, and A. Werner. The former called them *basic chromium erythro-salts.* They include : (1) bromide ; (2) dithionate ; and (3) nitrate.

(iii) *Dihydroxyaquatorethylenediamines,* $[Cr_2(OH)_2\,en_4]X_4$. They were studied by P. Pfeiffer and R. Stern. The salts include : (1) bromide ; and (2) iodide. P. Pfeiffer represented them by the formula :

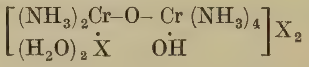


(iv) *Trihydroxyaquohexammines,* $[Cr_2(OH)_3(H_2O)(NH_3)_6]X_3$, or possibly $[Cr_4(OH)_6(NH_3)_{12}]X_6$. S. M. Jörgensen studied these salts and called them *chromium rhodoso-salts.* They were also studied by P. Pfeiffer, and J. Petersen. The salts include : (1) chloride, (2) its chloraurate, and (3) its chloroplatinate ; (4) bromide ; (5) iodide ; (6) polysulphide ; (7) sulphate ; (8) hydrosulphate ; (9) hydroxalate ; and (10) chromate. S. M. Jörgensen gave for the formula :



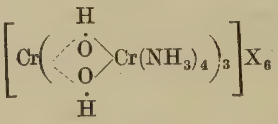
$$\left[\underset{(H_2O)_2OH}{(NH_3)_2\,Cr}-O-\underset{X}{Cr}(NH_3)_4\right]X_2$$

or



$$\left[\underset{(H_2O)_2X}{(NH_3)_2Cr}-O-\underset{OH}{Cr}\,(NH_3)_4\right]X_2$$

and P. Pfeiffer :



II.—**Trichromic salts** having three chromium atoms in the nucleus. Series of complex acetates, cyanoacetates, bromo-acetates, etc., were described by D. R. Camhi, J. A. Jwanowits, R. F. Weinland, G. Aschkinasy, and R. G. Krasnowskaja. In illustration, there are :

(i) *Hexacetatodihydroxytriammines,* $[Cr_3(CH_3COO)_6(OH)_2(NH_3)_3]X$, represented by the iodide prepared by R. F. Weinland and E. Büttner, and L. A. Welo.

(ii) *Hexacetatodihydroxytripyridines,* $[Cr_3Py_3(CH_3COO)_6(OH)_2]X$. These salts, prepared by R. F. Weinland and E. Gussmann, and L. A. Welo are represented by (1) hydroxystannichloride ; (2) chloroplatinate ; (3) iodide ; (4) nitrate ; (5) acetate ; (6) chloracetate ; (7) nitratacetate ; (8) ferricyanide ; (9) complex chromichromatodichromate ; and (10) permanganate.

(iii) *Chromic pentahydroxyaquodecammino-salts,* $[Cr_3(OH)_5(NH_3)_{10}(H_2O)](S_2O_3)_2.nH_2O$, and *chromic pentahydroxydiaquo-enneammino-salts, e.g.* $[Cr(OH)_5(NH_3)_9(H_2O)_2](S_2O_3)_2.3H_2O$ of P. Ray and P. B. Sarkar.

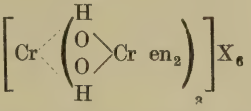
(iv) *Hexaformatodihydroxy-salts*, studied by L. A. Welo, R. Weinland and J. Lindner, etc.

(v) *Hexapropionatohydroxyfluoro-salts*, investigated by R. Weinland and J. Lindner.

III.—**Tetrachromic salts** having four chromium atoms in the nucleus.

(i) *Hexahydroxydodecammines—vide supra, trihydroxyaquohexammines.*

(ii) *Hexahydroxysexiesethylenediamines*, $[Cr_4(OH)_6\,en_6]X_6$. They were studied by P. Pfeiffer, and P. Pfeiffer and W. Vorster. The salts include: (1) chloride; (2) bromide; (3) iodide, and (4) its mercuri-iodide; (5) sulphate; (6) dithionate; (7) nitrate; (8) thiocyanate; and (9) chromate. P. Pfeiffer represented the constitution by the formula:



$$\left[Cr\left(\begin{matrix}H\\O\\O\\H\end{matrix}>Cr\ en_2\right)_3\right]X_6$$

About a dozen and a half salts, which have been reported, have not been fitted into A. Werner's system. When the salts are investigated more closely it may be possible to do something more with them. P. T. Cleve reported a *chromic tetramminosulphate*, $2Cr_2O_3.SO_3.4NH_3.24H_2O$; *chromic tetramminodinitrate*, $Cr_2O_3.N_2O_5.4NH_3.3H_2O$, *chromic diamminonitrate*, $2Cr_2O_3.N_2O_5.4NH_3.nH_2O$; and *ammonium chromic heptamminoctonitrate*, $2Cr(NO_3)_3.7NH_3.2NH_4NO_3.4\frac{1}{2}H_2O$; the *chromic diamminoxalate*, $Cr_2O_3.C_2O_3.2NH_3.8H_2O$, and *ammonium chromic hexamminotrioxalate*, $Cr_2(C_2O_4)_3.6NH_3.(NH_4)HCr_2O_4.1\frac{1}{2}H_2O$; and the *chromic heptamminonitratooxalate*, $2Cr(NO_3)(C_2O_4).7NH_3.3H_2O$; W. R. Lang and E. H. Jolliffe, *chromic quinquiesmethylaminotrichloride*, $CrCl_3.5CH_3NH_2$; W. R. Lang and C. M. Carson, *chromic quinquiesethylaminotrichloride*, $CrCl_3.5C_2H_5NH_2.H_2O$, and *chromic quaterethylamine*, $CrCl_3.4C_2H_5NH_2.H_2O$; and *chromic quaterethylenediaminotrichloride*, $CrCl_3.4C_2H_4(NH_2)_2H_2O$; O. Nordensjöld, *mercuric chromic sulphotrithiocyanatodiammine*, $Cr(SCy)_3(NH_3)_2.6HgS$; J. Sand and O. K. H. Burger, *chromic oxytetrathiocyanatotetrammine*, $Cr_2O(SCy)_4(NH_3)_4$; and *chromic oxytetrathiocyanatotetrapyridine*, $Cr_2O(SCy)_4Py_4$; E. A. Werner, *oxalatotriamminochromic acid*, $HCr(C_2O_4)_2(NH_3)_3.3H_2O$; *potassium oxalatotriamminochromate*, $KCr(C_2O_4)_2(NH_3)_3.3H_2O$; and *ammonium oxalatotriamminochromate*, $(NH_4)_5Cr_4(C_2O_4)_5(NH_3)_3.14H_2O$.

§ 25. The Complex Salts of Chromic Chloride

S. M. Jörgensen[1] treated mercuric chromic hexamminochloride—made by adding mercuric chloride to a hydrochloric acid soln. of chromic hexamminonitrate—with hydrogen sulphide, and obtained a liquid from which yellow crystals of **chromic hexamminotrichloride,** $[Cr(NH_3)_6]Cl_3.H_2O$, were obtained. The salt is freely soluble in water ; and when treated with hydrochloric acid, it forms the chloropentamminodichloride, $[Cr(NH_3)_5Cl]Cl_2$. W. Biltz and E. Birk gave 1·585 for the sp. gr. of the hexammine at 25°/4° and 175·8 for the mol. vol. Y. Shibata measured the absorption spectrum. S. Aoyama and co-workers studied the X-ray absorption and constitution. A. Werner and A. Miolati found that a mol of the salt in v-litres of water at 25° had the mol. conductivity μ ;

v . .	125	250	500	1000	2000
μ . .	353·5	388·6	418·8	441·7	463·6 mhos.

E. Birk studied the mol. vol. of the ammonia in the ammines. H. J. S. King calculated 180·0 for the ionic mobility at 0° and 370·2 at 25°. F. Ephraim and P. Mosimann discussed the solubilities of the hexammines; O. Stelling, the X-ray spectrum; and H. Lessheim and co-workers, the electronic structure. A. Benrath found that in the presence of hydrochloric acid the stable phase is $[Cr(NH_3)_5Cl]Cl_2$. P. Pfeiffer also prepared *chromic trisethylenediaminotrichloride,* $[Cr\,en_3]Cl_3,3\frac{1}{2}H_2O$. O. T. Christensen obtained **chromic aquopentamminotrichloride,** $[Cr(H_2O)(NH_3)_5]Cl_3$, from a soln. of the base in hydrochloric acid. S. M. Jörgensen also prepared this salt. The orange-yellow crystals are freely soluble in water. The dil. aq. soln. is decomposed when boiled, but the acidified soln. is more stable. When boiled with hydrochloric acid, the chloropentamminochloride is formed. All three chlorine atoms are immediately precipitated by the addition of silver nitrate. F. Ephraim and W. Ritter obtained the salt by the action of an ammoniacal soln. of ammonium nitrate on potassium or ammonium chromic chloride. H. J. S. King also prepared this salt; and he gave for the conductivity, μ mhos, of a mol. of the salt in v litres at 0° :

v . .	32	64	128	256	512	1024
μ . .	169·5	186·3	197·6	218·4	232·9	247·8

For the mol. conductivity, μ, of soln. of a mol of the salt in v litres of water at 25°, A. Werner and A. Miolati gave :

v . .	125	250	500	1000	2000
μ . .	221·0	239·3	252·0	261·0	271·6

Values were also obtained by H. J. S. King who gave 174·3 for the ionic mobility at 0° of the $[Cr(NH_3)_5(H_2O)]^{\cdots}$-ion. F. Ephraim and W. Ritter found that the salt absorbs ammonia at a low temp., and the decomposition curve shows breaks corresponding with a tetrammine, and doubtful breaks for the hexammine and diammine. A. Benrath found that the stable phase in the presence of hydrochloric acid is $[Cr(NH_3)_5Cl]Cl_2$. P. Pfeiffer prepared **chromic diaquotetramminotrichloride,** $[Cr(H_2O)_2(NH_3)_4]Cl_3$, from a hydrochloric acid soln. of chromic hydroxyaquotetramminodithionate. The brick-red crystalline powder is soluble in water. The conc. aq. soln. gives an orange-red precipitate with potassium cobalticyanide and a brick-red precipitate with conc. hydrochloric or hydrobromic acid. Silver nitrate precipitates all three chlorine atoms. The salt gradually passed into the aquochlorotetramminodichloride. E. H. Riesenfeld and F. Seemann, and F. Frowein prepared **chromic triaquotriamminotrichloride,** $[Cr(NH_3)_3(H_2O)_3]Cl_3$, by dissolving chromic tetroxytriammine in dil. hydrochloric acid and passing hydrogen chloride into the resulting soln. After a time, bright red, needle-shaped crystals of the triaquotriamminotrichloride separate. If the hydrogen chloride is passed in for too long a time, the soln. becomes green in colour, and crystals of either the dichromic or the grey dichloroaquotriamminochloride, are obtained. A. Werner obtained the salt by dissolving chromium triamminotetroxide in hydrochloric acid (1 : 4) and saturating the cold soln. with hydrogen chloride; he also obtained it by covering a mixture of a gram of dichloroaquotriamminochloride and 8 c.c. of water with 5 c.c. of pyridine, and adding solid potassium iodide; the resulting chromium triamminotriaquohydroxyiodide is treated with conc. hydrochloric acid, and the resulting triamminotriaquotrichloride is purified by passing hydrogen chloride through the aq. soln. F. Frowein found that the dichloroaquotriamminochloride in aq. soln. gradually changes into the chlorodiaquotriamminodichloride ; and this, in turn, into the triaquotriamminotrichloride. The changes can be followed by the change of colour of the soln., that of the monoaquo-salt being blue, that of the diaquo-salt reddish-violet, and that of the triaquo-salt red. These changes are more rapid the more dil. the soln. The conductivity of the monoaquo-compound is lowest, that of the triaquo-compound highest, so that the change is accompanied by a gradual increase in conductivity of the soln. No direct transformation of the mono- into the tri-aquo-salt occurs, but the diaquo-salt is always the first hydration product of the monoaquo-compound. The measurements agree with the hypothesis that the compounds contain no water outside the inner sphere, that is, they are purely co-ordinated compounds. The soln. of the triaquo-compound undergoes slow decomposition, the conductivity curve first showing a maximum, followed by a minimum. Deposition of chromium hydroxide eventually takes place, but intermediate complex compounds are probably first formed. A. Werner also prepared **chromium triamminotriaquodichloronitrate,** $[Cr(H_2O)_3(NH_3)_3]Cl_2(NO_3)$, and also **chromium triamminotriaquotriperchlorate,** $[Cr(H_2O)_3(NH_3)_3](ClO_4)_3$.

P. Pfeiffer and R. Stern prepared **chromic cis-diaquobisethylenediaminotrichloride,** $[Cr\ en_2(H_2O)_2]Cl_3.2H_2O$, and P. Pfeiffer and R. Prade obtained the **trans-salt ;** A. Werner and J. L. Klein obtained **chromic tetraquodiamminotrichloride,** $[Cr(H_2O)_4(NH_3)_2]Cl_3$, from a hydrochloric acid soln. of the bromide. The pale red, monoclinic prisms are freely soluble in water, and insoluble in alcohol. P. Pfeiffer, and P. Pfeiffer and M. Tapuach prepared **chromic tetraquodipyridinotribromide,** $[CrPy_2(H_2O)_4]Br_3.2H_2O$. The preparation of **chromic hexaquotrichloride,** $[Cr(H_2O)_6]Cl_3$, by N. Bjerrum, A. Werner and A. Gubser, A. Werner and R. Huber, A. Weinland and R. Krebs, R. F. Weinland and T. Schumann, and P. Pfeiffer has been previously described.

H. J. S. King prepared rose-red needles of **chromic hydroxypentamminochloride,** $[Cr(NH_3)_5(OH)]Cl_2.H_2O$, by dissolving the aquopentamminochloride in conc. ammonia, and precipitating with alcohol. He gave for the conductivity, μ mho, of a mol of the salt in v litres at 0° and 25° :

v . .	32	64	128	256	512	1024
0° . .	108·8	119·0	127·5	134·9	138·8	147·2
25° . .	206·2	225·7	239·0	253·0	261·9	274·6

He calculated 73·3 for the ionic mobility at 0° and 131·8 at 25°. P. Pfeiffer and R. Stern prepared **chromic cis-hydroxyaquobisethylenediaminodichloride,** $[Cr\ en_2(H_2O)(OH)]Cl_2.H_2O$; P. Pfeiffer, **chromic hydroxydiaquodipyridinodichloride,** $[CrPy_2(H_2O)_2(OH)]Cl_2$; and O. T. Christensen, **chromic nitritopentamminodichloride,** $[Cr(NH_3)_5(NO_2)]Cl_2$, by the action of dil. nitric acid on the chloride of the series. A. Werner and A. Miolati found the electrical conductivity of soln. with a mol of the salt in 125, 250, 500, 1000, and 2000 litres of water at 25° to be respectively μ=221·0, 239·3, 252·0, 261·0, and 271·6.

S. M. Jörgensen prepared **chromic chloropentamminodichloride,** $[Cr(NH_3)_5Cl]Cl_2$, by reducing, say, 25 grms. of violet chromic chloride with hydrogen at a red-heat, and treating the product with a soln. of ammonium chloride in conc. aq. ammonia. Air is then passed through the blue liquid until oxidation is complete. Two litres of hydrochloric acid are added and the mixture is boiled for a few minutes when the salt separates as a carmine-red powder. This is washed with a mixture of hydrochloric acid (1 : 1), dissolved in dil. sulphuric acid, and filtered into a great excess of cold, conc. hydrochloric acid. The precipitate is boiled with hydrochloric acid, washed first with cold acid and water, then with alcohol, and finally dried in air at ordinary temp. F. Ephraim and W. Ritter obtained the salt by the action on potassium or ammonium chromic chloride of an ammoniacal soln. of ammonium nitrate. O. T. Christensen obtained it by reducing a soln. of potassium dichromate with alcohol and hydrochloric acid, and treated the clear liquid in the absence of air with conc. hydrochloric acid and zinc. The blue liquid was then digested with ammonium chloride and conc. ammonia, and air passed through the liquor. The soln. was then boiled a short time with conc. hydrochloric acid. O. T. Christensen, and W. R. Lang and C. M. Carson also made the same salt by digesting violet chromic chloride with liquid ammonia. A. Werner and J. von Halban, S. M. Jörgensen, and O. T. Christensen also prepared this salt by the action of hydrochloric acid on some of the other chromic ammines. S. M. Jörgensen described the salt as a red crystalline powder consisting of octahedra of sp. gr. 1·687. R. Klement gave 1·696 for the sp. gr. and 143·7 for the mol. vol. Y. Shibata measured the absorption spectrum. A. Werner and A. Miolati found that a mol of the salt in v litres of water at 25° has the mol. conductivity, μ :

v	125	250	500	1000	2000
μ	221·7	239·0	250·5	260·2	269·9

H. J. S. King gave for the conductivity, μ mhos, of a mol of the salt in v litres :

	v	64	128	256	512	1024
μ	0°	123·1	131·1	137·2	142·3	147·6
	25°	230·3	244·5	255·0	264·4	276·8

The ionic mobility at 0° is 75·2 and at 25°, 139·7. E. Rosenbohm found the magnetic susceptibility to be $25{\cdot}76\times10^{-6}$ mass units ; and L. A. Welo gave $24{\cdot}80\times10^{-6}$. A. Benrath found that the salt is stable in the presence of hydrochloric acid. S. M. Jörgensen found that 100 grms. of water at 16° dissolve 0·65 grm. of the salt forming a violet-red soln. which, when exposed to light, deposits hydrated chromic oxide. When the soln. is kept in the dark, or boiled, it passes into the aquochlorotetramminodichloride. When the aq. soln. is boiled it forms the aquopentamminochloride ; boiling soda-lye precipitates chromic hydroxide. The rate of hydrolysis of the salt was investigated by A. Werner and A. Miolati, A. B. Lamb and J. W. Marden, H. Freundlich and H. Pape, and H. Freundlich and R. Bartels. S. M. Jörgensen added that the aquochlorotetramminodichloride gives the following reactions : With sodium hypochlorite, nitrogen is evolved, and the chromium is oxidized to chromic acid. Its soln. gives a precipitate with conc. hydrochloric acid, owing to the insolubility of the chloride in acid. With hydrobromic acid, it gives a crystalline precipitate of the bromide, and with solid potassium iodide one of the iodide. When boiled with potassium cyanide, it turns yellow. Conc. nitric acid precipitates the chloro-nitrate. Hydrosilicofluoric acid throws down the red crystalline chlorofluosilicate. Platinic chloride precipitates, even from a very dil. soln., the chloropurpureochromium platinochloride. Sodium bromoplatinate gives an analogous precipitate. Mercuric chloride gives red needles of the double salt. Precipitates are also produced by potassium mercuric bromide and iodide, by sodium dithionate, potassium chromate, and dichromate, ammonium molybdate, and phosphomolybdate, and by picric and oxalic acids. In these respects this salt closely resembles the analogous cobalt salt. On treatment with silver nitrate only two atoms of chlorine are removed, and the chloro-nitrate is formed. By rubbing the solid chloride with silver oxide and water the aquochlorotetramminodichloride is formed. S. M. Jörgensen also prepared the sulphide, sulphate, hydrosulphate, dithionate, fluosilicate, nitrate, bromide, iodide, oxalate, ferrocyanide, and chromate, as well as complex mercury and platinic halides of the chromic chloropentammines. F. Ephraim and W. Ritter found that the chloropentamminodichloride does not absorb ammonia gas.

In 1858, E. Frémy obtained a salt which P. T. Cleve showed to be **chromic chloroaquotetramminodichloride,** $[Cr(NH_3)_4(H_2O)Cl]Cl_2$. It was prepared by allowing a sat. soln. of chromium chloride in aq. ammonia to stand in a closed vessel until the liquid acquired a red colour; it was then exposed to the air when it deposited a dark reddish-violet powder. The soln. of the salt in hydrochloric acid, when treated with an excess of conc. hydrochloric acid, furnished rose-red crystals of the aquochlorotetramminodichloride. S. M. Jörgensen obtained the salt by heating a conc. aq. soln. of 100 grms. of ammonium dichromate with 300 c.c. of hydrochloric acid of sp. gr. 1·17, 200 grms. of ammonium chloride, and 60–70 c.c. of alcohol, and evaporating to dryness. The product was digested for 24 hours with a litre of conc. ammonia; the residue was dissolved in hydrochloric acid, and treated anew with ammonia. The ammoniacal soln. was mixed with 4 litres of conc. hydrochloric acid; the precipitate was freed from ammonium chloride by hydrochloric acid (1 : 1). The mixture was dissolved in water and treated with a soln. of ammonium sulphate (1 : 5), and the precipitate washed with cold water; and digested with hydrochloric acid (1 : 1). S. M. Jörgensen also obtained the salt as a by-product in preparing the oxalatotetramminonitrate. P. Pfeiffer and S. Basci agitated 100 grms. of green hexahydrated chromic chloride with 155 c.c. of pyridine; and after adding 600 c.c. of water, allowed the mixture to stand for 7 to 10 hrs. Ten grams of the diaquodipyridinochloride were digested with 56 c.c. of 25 per cent. aq. ammonia at 45° to 48°. The deep reddish-violet soln. was treated with 68 c.c. of hydrochloric acid of sp. gr. 1·19. After standing 4 or 5 hrs. at ordinary temp., the prismatic crystals were separated from the mother-liquor. P. Pfeiffer obtained the same salt from the diaquotetramminochloride and hydrochloric acid. The deep red rhombic crystals are stable in air, but not if exposed to light. J. Peterson obtained a mol. wt. 262 by the f.p. method when the theoretical value is 251·5. Y. Shibata measured the absorption spectrum. A. Werner and A. Miolati found that a mol of the salt in v litres of water had the mol. conductivity, μ, at 25°,

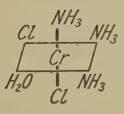
v . .	125	250	500	1000	2000
μ . .	212·6	231·6	245·6	261·2	274·8

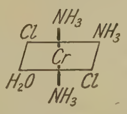
S. M. Jörgensen found that 100 grms. of water at 15° dissolve 6·4 grms. of the salt. The salt is decomposed when the soln. in water or alkali-lye is boiled; hydrochloric acid precipitates the salt from the aq. soln. Oxalic acid precipitates from the soln., after standing some weeks, $Cr_2(C_2O_4)_3.6NH_3.3H_2O$; ammonium oxalate precipitates from the warm soln. chromic oxalate tetramminochloride and with potassium thiocyanate, P. Pfeiffer and M. Tilgner obtained chromic dithiocyanatotetramminothiocyanate; with pyridine and sodium dithionate, P. Pfeiffer obtained chromic hydroxyaquotetramminodithionate. P. T. Cleve found that conc. sulphuric acid expels only two-thirds of the chlorine as hydrochloric acid; and S. M. Jörgensen, that a nitric acid soln. of silver nitrate precipitates only two-thirds of the chlorine as silver chloride. There are also the sulphate, sulphide, nitrate, fluosilicate, bromide, iodide, oxalate, and chromate as well as complexes of the chloride with the mercuric and platinic chlorides of the aquochlorotetrammines. N. Bjerrum, R. F. Weinland and R. Krebs, R. F. Weinland and T. Schumann, and A. Recoura described **chromic chloropentaquodichloride,** $[Cr(H_2O)_5Cl]Cl_2$—*vide supra.* H. J. S. King found the conductivity, μ mhos, of a mol of the salt in v litres, to be:

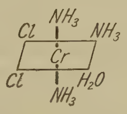
	v . .	64	128	256	512	1024
μ	0° . .	—	134·8	142·1	146·8	151·2
	25° . .	232·3	247·7	261·5	272·9	280·6

B. Klement gave 1·961 for the sp. gr., and 143·7 for the mol. vol. A. Werner and A. Miolati found that a soln. of a mol of the salt in 125, 250, 500, 1000, and 2000 litres of water at 25° had the mol. conductivity μ=235·7, 257·5, 270·6, 280·1, and 283·6 respectively. P. T. Cleve prepared **chromic bromoaquotetramminodichloride,** $[Cr(NH_3)_4(H_2O)Br]Cl_2$, by the action of fuming hydrochloric acid on the bromide. S. M. Jörgensen prepared **chromic iodopentamminodichloride,** $[Cr(NH_3)_5I]Cl_2$, by the action of hydrochloric acid on the iodide. A. Werner and A. Miolati found that a mol of the salt in 125, 250, 500, 1000, and 2000 litres of water at 25° had the mol. conductivity $\mu=273{\cdot}8$, $292{\cdot}5$, $312{\cdot}1$, $326{\cdot}9$, and $342{\cdot}8$ respectively. The chloroplatinate was also obtained. F. Frowein, and E. H. Riesenfeld and F. Seeman prepared **chromic chlorodiaquotriamminodichloride,** $[Cr(NH_3)_3(H_2O)_2Cl]Cl_2$, by boiling an aq. soln. of one of the isomeric dichloroaquotriamminochlorides, and evaporating the liquid. The violet-red crystals form a red soln. with water. For the conductivity and the action of water, *vide supra*, the triaquotriamminotrichloride. A. Werner and J. von Halban prepared **chromic thiocyanatopentamminodichloride,** $[Cr(NH_3)_5(SCy)]Cl_2$.

F. Frowein, and E. H. Riesenfeld and F. Seemann prepared **chromic dichloroaquotriamminochloride,** $[Cr(NH_3)_3(H_2O)Cl_2]Cl$, by adding conc. hydrochloric acid to a soln. of chromium triamminotetroxide in well-cooled, dil. hydrochloric acid, and allowing the soln. to stand for some time. The reddish-violet, dichroic crystals form a blue soln. with water. If conc. hydrochloric acid is used instead of the dil. acid, a light green soln. is obtained, from which grey, needle-shaped crystals of a second modification of the above chloride separate, which is scarcely soluble in cold water, but dissolves in hot water to a red soln. A third modification is obtained by heating a hydrochloric acid soln. of the first chloride for some time at 60°. The soln. gradually becomes green in colour, and on evaporation in a desiccator, dark green crystals are obtained which dissolve in water to a green soln. None of these three chlorides readily loses water, which is therefore probably contained in the complex in all three salts. In all probability they are stereoisomerides:







At present it is impossible to say which formula corresponds with which isomeride. For the electrical conductivity, and hydrolysis, *vide supra*, the triaquotriamminotrichloride. F. Pintus prepared complexes with alcohol, $[Cr(C_2H_5.OH)_3Cl_3]$, and with thiourea, $[Cr(C_3SN_2H_4)_3Cl_3]$.

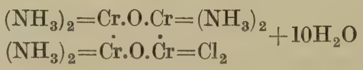
A. Werner and J. L. Klein, and A. Werner and J. V. Dubsky prepared **chromic dihydroxydiaquodiamminochloride,** $[Cr(OH)_2(H_2O)_2(NH_3)_2]Cl.H_2O$, by adding ammonia or pyridine to a conc. aq. soln. of the tetraquodiamminochloride; or by treating the bromide of the series with rubidium chloride. The crystals are lilac or reddish-violet. R. F. Weinland and co-workers, and A. Recoura also prepared the corresponding sulphate. P. Pfeiffer, and P. Pfeiffer and W. Osann prepared **chromic dihydroxydiaquodipyridinochloride,** $[CrPy_2(H_2O)_2(OH)_2]Cl$; and E. Weinmann, **chromic dihydroxydiaquoethylenediaminochloride,** $[Cr(H_2O)_2en(OH)_2]Cl$. A. Werner and J. L. Klein obtained **chromic dichlorodiaquodiamminochloride,** $[Cr(H_2O)_2(NH_3)_2Cl_2]Cl$, in pale green plates by the action of chlorine on a 25 per cent. aq. soln. of the tetrathiocyanatodiammine. The salt is soluble in water and with silver nitrate only one-third of the chlorine is precipitated. P. Pfeiffer and P. Koch, P. Pfeiffer and W. Stern, P. Pfeiffer and A. Trieschmann, and P. Pfeiffer prepared **chromic cis-dichlorobisethylenediaminochloride,** $[Cr\,en_2Cl_2]Cl.H_2O$, and a complex with antimonic and platinic chlorides; P. Pfeiffer, and P. Pfeiffer and P. Koch also prepared the **trans-salt**—anhydrous, monohydrate, hydrochloride, and chloroplatinate. A. Werner obtained **chromic dichloroaquotriamminochloride,** $[Cr(NH_3)_3(H_2O)Cl_2]Cl$, as well as the corresponding iodide, sulphate, and nitrate. P. Pfeiffer and M. Tapuach obtained **chromic dichlorodiaquodipyridinochloride,** $[CrPy_2(H_2O)_2Cl_2]Cl$, and a complex with pyridinium chloride, as well as the bromide, and nitrate. A. Werner and A. Gubser, P. Pfeiffer, N. Bjerrum, and R. F. Weinland and K. Feige discussed **chromic tetraquodichlorochloride,** $[Cr(H_2O)_4Cl_2]Cl$, previously described. P. Pfeiffer and M. Tilgner prepared **chromic dithiocyanatotetramminochloride,** $[Cr(NH_3)_4(SCy)]Cl$; P. Pfeiffer and P. Koch, **chromic cis-dithiocyanatobisethylenediaminochloride,** $[Cr\,en_2(SCy)_2]Cl.H_2O$, and also the

trans-salt ; and P. Pfeiffer and S. Basci, **chromic oxalatotetramminochloride,** $[Cr(NH_3)_4(C_2O_4)]Cl$.

O. T. Christensen prepared **chromic hydroxydecamminopentachloride,** $[Cr_2(NH_3)_{10}(OH)]Cl_5.H_2O$, by treating the corresponding bromide with hydrochloric acid (1 : 1) ; and by the action of air on an ammoniacal soln. of ammonium chloride and chromic chloride. It was also obtained by P. Pfeiffer. J. Petersen gave for the average mol. wt. by the f.p. process 308, when the theoretical value is 469·5 ; and from the electrical conductivity process, the molecule furnishes 5·85 ions in dil. soln. A complex chloroplatinate, and a chloroiodide, were also prepared. S. M. Jörgensen prepared **chromic trihydroxyaquohexamminotrichloride,** $[Cr_2(OH)_3(H_2O)(NH_3)_6]Cl_3.H_2O$, as follows :

> A soln. of chromous chloride, prepared by reducing a soln. of potassium dichromate with zinc and hydrochloric acid, is forced by hydrogen press. into a vessel containing a mixture of 700 grms. ammonium chloride, and 750 c.c. of aq. ammonia, sp. gr. 0·91. The vessel, entirely filled with this mixture, is closed by a stopper through which passes a delivery tube opening under water. The vessel is surrounded by cold water to moderate the reaction. The evolution of hydrogen takes place slowly, and ceases in about 24 hrs. The undissolved ammonium chloride is covered with trihydroxyaquohexamminotrichloride, a portion of which is also contained in the soln. from which it may be precipitated by alcohol ; the precipitate is washed with alcohol, and dried.

The salt was also prepared by P. Pfeiffer. J. Petersen found the mol. wt. 340 to 406 by the f.p. method—theoretical 364·5, and the electrical conductivity indicated that 3·76 ions per mol. are formed. The carmine-red prisms slowly lose a mol. of water over sulphuric acid ; at 100°, the salt gradually decomposes ; 100 parts of water at 18° dissolve 9·4 grms. of salt ; it is decomposed by boiling water ; boiling hydrochloric acid forms aquochlorotetramminochloride ; conc. hydrobromic acid precipitates the bromide ; solid potassium iodide, the iodide ; dil. sulphuric acid followed by alcohol precipitates the sulphate ; ammonium sulphate gives no precipitate ; hydrofluosilicic acid gives a red precipitate ; hydrochloroplatinic acid, forms acicular crystals ; hydrochloric acid, a reddish-brown precipitate ; potassium dichromate, an orange-yellow precipitate ; sodium pyrophosphate, a pale red precipitate soluble in excess ; sodium hydrophosphate, no precipitate ; ammonium thiocyanate, rhombic plates ; potassium ferrocyanide, lilac-coloured precipitate ; and potassium ferricyanide, a brown precipitate. P. Pfeiffer and W. Vorster prepared **chromic hexahydroxysexiesethylenediaminehexachloride,** $[Cr_4(OH)_6en_6]Cl_6.6H_2O$. M. Z. Jovitschitsch prepared **chromic dioxyhexamminodichloride,** $Cr_4O_2(NH_3)_6Cl_2.10H_2O$, by dissolving the precipitate, obtained by adding ammonia to a chromic salt, in an excess of ammonia, and adding hydrochloric acid, and then alcohol. The violet-red precipitate is soluble in water, but only after standing a few hours will the soln. give a precipitate with silver nitrate. It is assumed that the salt is constituted :



$$\begin{array}{l}(NH_3)_2{=}Cr.O.Cr{=}(NH_3)_2\\ \qquad\quad\ \vdots\qquad\ \vdots\\ (NH_3)_2{=}Cr.O.Cr{=}Cl_2\end{array}+10H_2O$$

A. Werner found that when chromium triamminotetroxide, $CrO_4(NH_3)_3$, is added to cold, conc. hydrochloric acid, a grey or bluish-grey precipitate is formed —probably a mixture of chromium triamminodichloroaquochloride and triamminotrichloride—and the filtrate, on standing for two days, deposits chromium triamminotrichloride, $Cr(NH_3)_3Cl_3$, in dark blue crystals, tinged with green. The X-ray spectra of this salt and the corresponding pyridine salt $[Cr(Py)_3Cl_3]$, were studied by O. Stelling. According to A. Werner, the trichlorotriammine is almost insoluble in cold water ; it dissolves in hot water forming a blue soln. which furnishes a series of chromium **triamminodichloroaquo-salts** when treated with the appropriate reagents.

Thus, **chromium triamminodichloroaquochloride,** $[Cr(H_2O)(NH_3)_3Cl_2]Cl$, is formed in brown-leaflets which give a blue soln. with water. The salt is also obtained by the action of conc. hydrochloric acid in the presence of glacial acetic acid on chromium triamminotetroxide. There are also **chromium triamminodichloroaquonitrate,** $[Cr(H_2O)(NH_3)_3Cl_2]NO_3$; **chromium triamminodichloroaquosulphate,** $[Cr(H_2O)(NH_3)_2Cl_2)_2SO_4$; **chromium triamminodichloroaquoiodide,** $[Cr(H_2O)(NH_3)_2Cl_2]I$; the basic iodide, **chromium triamminotriaquodihydroxyiodide,** $[Cr(H_2O)_3(NH_3)_3](OH)_2I$, and **chromium triamminotriaquotribromide,** $[Cr(H_2O)_3(NH_3)_3]Br_3$.

H. I. Schlesinger and R. K. Worner heated chromium chloropentamminochloride in air, hydrogen, carbon dioxide, or ammonia, and found that it furnishes chromium triamminotrichloride. Unless the temp. is carefully controlled, the reaction proceeds further. The black substance, reported by C. E. Ufer, and H. Schrötter, is formed. If the pentammine is heated in a stream of dry hydrogen chloride, a very rapid reaction occurs at about 270° with considerable evolution of heat and is accompanied by a marked colour change of the material from pink to green. If heating is discontinued at this point, the product washed with cold water to which a little hydrochloric acid has been added, and then dried with alcohol and ether, a very insoluble green substance, chromium trichlorotriammine is obtained. The triammine differs from that prepared by A. Werner. His compound is blue-green, dissolves fairly readily in warm water and especially easily in warm dil. hydrochloric acid to give a deep blue soln. of trichloroaquotriamminochloride ; that of A. Werner is insoluble in hydrochloric acid or in water, but with the latter it slowly reacts to give a pink soln. which has since been shown to contain chromic diaquotetramminochloride. Here evidently is a case of isomerism of a type not frequently encountered, but whether it is stereoisomerism, possible according to A. Werner's theory, or is what is often called " polymerization isomerism," cannot be decided because of the insolubility of the compounds in question. Attempts to remove some of the three remaining molecules of ammonia from the co-ordination sphere show the firmness with which chromium retains the co-ordination number 6. When the triammine is heated to 175° in a stream of hydrogen chloride, ammonia is not withdrawn from the compound, but hydrogen chloride is quantitatively absorbed to give a reddish-purple very hygroscopic crystalline material which may be considered to be **ammonium chromic hexachloride,** $(NH_4)_3[CrCl_6]$. The substance is insoluble in all solvents except water, with which it reacts almost instantly to produce a deep green soln. presumably of hydrated chromic chloride. In favour of the argument that the ammonium compound is a salt of the complex ion $[CrCl_6]'''$, anhydrous chromic chloride, alone or when mixed with ammonium chloride, reacts with liquid ammonia to give a mixture of hexammine and chloropentammine chromic chlorides without the intermediate formation of a soln. What is called ammonium chromic hexachloride dissolves readily in liquid ammonia to give a green soln. which is transformed to the pentammine only after complete evaporation of the liquid. Anhydrous chromic chloride reacts exceedingly slowly with dry gaseous ammonia ; the new compound reacts rapidly at ordinary temp. to give the pentammine. Double salts should possess a colour which is the summation of the colours of the constituent salts ; the compound here prepared is decidedly different in colour from any known form of chromic chloride, the only coloured constituent. In this instance, then, chromium, rather than changing its co-ordination number as the result of removal of ammonia, takes up hydrogen chloride, and the ammonia, although removed from the co-ordination sphere, remains in the molecule. If the triamminotrichloride is treated with oxalic acid or an oxalate, **ammonium chromium triammino - oxalatochloride,** $(NH_4)_6[Cr_2(NH_3)_3(C_2O_4)Cl_{10}]$, is formed.

A. Johnsen[2] obtained no isomorphous mixtures of ammonium chloride and violet chromic chloride, but with green hexahydrated chromic chloride, the ammonium chloride crystals are coloured green. J. W. Retgers obtained solid soln. of both green and violet chromic chlorides from aq. soln. N. Larsson prepared **ammonium chromium tetrachloride,** $NH_4Cl.CrCl_3.6H_2O$, or $[CrCl(H_2O)_5]Cl_2.NH_4Cl.H_2O$, by boiling a soln. of a mixture of chromic chloropentaquodichloride and ammonium chloride, and passing hydrogen chloride through the soln. cooled by a freezing mixture. G. Neumann prepared **ammonium chromic pentachloride,** $2NH_4Cl.CrCl_3.H_2O$, or $(NH_4)_2[CrCl_5(H_2O)]$, by adding ammonium chloride to a soln. of chromic chloride in 96–97 per cent. alcohol, and passing hydrogen chloride through the liquid heated on a water-bath with a reflux condenser. The violet, hygroscopic crystals of the *monohydrate* are probably rhombic. They are decomposed by water. A. Werner and A. Gubser represent this series of salts by $[Cr(H_2O)Cl_5](NH_4)_2$. R. F. Weinland and T. Schumann found that when hydrogen chloride is passed into an ice-cold soln. of equimolar proportions of green hexahydrated chromic chloride and ammonium chloride, green rectangular plates of the *hexahydrate* are formed. The salt is deliquescent, and turns red when warmed. A soln. of the salt acidified with nitric acid, and treated with silver nitrate deposits three-fifths of the chlorine as silver chloride. Hence the constitution of the salt is taken to be $(NH_4)_2[Cr(H_2O)_4Cl_2]Cl_3.2H_2O$. H. I. Schlesinger and R. K. Worner prepared **ammonium chromic hexachloride,** $(NH_4)_3CrCl_6$, in hygroscopic crystals, by heating chromic trichlorotriammine in hydrogen chloride at 175°. It reacts with ammonia to furnish chromic chloropentamminodichloride.

F. Ephraim and W. Ritter found that ammonia acts on potassium chromic aquopentachloride forming a greyish-violet mass of chromic hydroxypentamminochloride. This dissolves in water, and nitric acid precipitates from the cherry-red soln., first chromium nitratopentamminodinitrate, and then chromic nitrataquotetramminodinitrate in a 27 per cent. yield; while hydrochloric acid precipitates from the cherry-red soln., the chloropentamminochloride in 40 per cent. yield. Similar results were obtained with the ammonium salt. F. Ephraim and W. Ritter suggest that ammonium hydroxypentachloride is formed as an intermediate compound. No evidence was obtained of the formation of ammines of the double salts.

A. Werner and A. Gubser[3] obtained **lithium chromium pentachloride,** $2LiCl.CrCl_3.5H_2O$, that is, $Li_2[Cr(H_2O)Cl_5].4H_2O$, as in the case of the ammonium salt, by passing hydrogen chloride into a soln. of 5 grms. of lithium chloride, and 17 grms. of hexahydrated chromic chloride. The red, hygroscopic powder is easily soluble in alcohol forming a green soln.; with water, the soln. is transiently red. At 0°, the salt gives no precipitate with silver nitrate when that salt is first added. N. Larsson found that **lithium chloropentaquodichloride,** $[CrCl(H_2O)_5]Cl_2.LiCl.nH_2O$, prepared as in the case of the ammonium salt, is very hygroscopic. J. J. Berzelius reported that when a soln. of sodium dichromate, hydrochloric acid, and alcohol is evaporated on the water-bath, a green mass of **sodium chromium tetrachloride,** $NaCrCl_4$, is formed, and it becomes violet on a sand-bath; N. Larsson obtained the salt **sodium chlorotetraquodichloride,** $[CrCl_2(H_2O)_4]Cl_2.NaCl.nH_2O$, as in the case of the sodium salt. J. J. Berzelius also prepared reddish-violet crystals of **potassium chromium tetrachloride,** $KCrCl_4$, in a similar manner; and found that the salt is decomposed when the aq. soln. is evaporated. L. Godefroy regarded this salt as a mixture of the pentachloride with chromic chloride. N. Larsson did not obtain $[CrCl(H_2O)_5]Cl_2.KCl.nH_2O$ by the method employed for the ammonium salt. L. Godefroy prepared **potassium chromium pentachloride,** $K_2CrCl_5.H_2O$, or $K_2[Cr(H_2O)Cl_5]$, by passing chlorine for 5 or 6 hrs. through a soln. of 300 grms. of powdered potassium dichromate and 700 grms. of alcohol; and G. Neumann obtained it by passing hydrogen chloride through a soln. of chromic and potassium chlorides in 96 to 97 per cent. alcohol warmed on a water-bath. The reddish, or violet-red crystalline powder is stable in air; it can be crystallized by heating it with 40 per cent. hydrochloric acid in a sealed tube at 120° to 130°. The crystals are probably rhombic; very hygroscopic; and are decomposed by water, forming potassium chloride and an oxychloride. For the action of ammonia, *vide supra,* the ammonium salt. J. J. Berzelius treated sodium chromium tetrachloride with alcohol, and obtained rose-red **sodium chromium hexachloride,** Na_3CrCl_6.

E. Zettnow, and J. J. Berzelius obtained **potassium chromium hexachloride,** K_3CrCl_6, in an analogous manner ; and E. Frémy, found that when a mixture of potassium dichromate, mixed with charcoal, is heated in chlorine gas, chromic chloride sublimes, and the hexachloride remains. The salt is soluble in water, and at the same time is decomposed into its constituent chlorides. L. Godefroy said that the hexachloride is really a mixture of the pentachloride and potassium chloride.

N. Larsson prepared **rubidium chromium tetrachloride,** $RbCl.CrCl_3.5H_2O$, or $[CrCl(H_2O)_5]Cl_2.RbCl$, as in the case of the corresponding ammonium salt ; and similarly with **cæsium chromium tetrachloride,** $CsCl.CrCl_3.5H_2O$, or $[CrCl(H_2O)_5]Cl_2.CsCl$. G. Neumann prepared **rubidium chromium pentachloride,** $Rb_2CrCl_5.H_2O$, or $Rb_2[Cr(H_2O)Cl_5]$, by the method employed for the potassium salt ; and A. Werner and A. Gubser, by passing hydrogen chloride into a soln. of the constituent chlorides. The *monohydrate* furnishes reddish-violet crystals, sparingly soluble in cold water ; and readily soluble in hot water forming a green soln. By working with the soln. at 0°, A. Werner and A. Gubser obtained the *octohydrate*, $[(ClRb.Cl)_2Cr(H_4O_2)_4]Cl$, in green, prismatic crystals, which lose water when confined over sulphuric acid, and deliquesce with decomposition in air. Only three-fifths of the chlorine is at first precipitated by silver nitrate. N. Larsson prepared the compound $[CrCl_2(H_4O_2]Cl.2RbCl$ from a soln. of chromic dichloroaquochloride and rubidium chloride, cooled with a freezing mixture, and treated with hydrogen chloride. It is stable in air ; alcohol extracts chromic chloride ; at 85° it forms $Rb_2[CrCl_5(H_2O)]$. H. L. Wells and B. B. Boltwood prepared **cæsium chromium pentachloride,** $Cs_2CrCl_5.H_2O$, or $Cs_2Cr(H_2O)Cl_5$, by passing hydrogen chloride into a warm soln. of the component chlorides. The *monohydrate* forms violet crystals which are stable in air, and do not lose water at 160°. They dissolve slowly in water forming a green soln. which, on evaporation, yields crystals of the *tetrahydrate* which A. Werner and A. Gubser represent by the formula $(ClCsCl)_2Cr(H_2O)_4Cl$, because only three-fifths of the chlorine is at first precipitated by silver nitrate. This subject was discussed by R. F. Weinland and A. Koch. H. St. C. Deville obtained green crystals by fusing a mixture of chromic and sodium chlorides.

S. M. Jörgensen prepared **chromic hydroxydecamminotrichlorodichloraurate,** $[Cr_2(OH)(NH_3)_{10}]Cl_3(AuCl_4)_2$, in reddish-yellow needles by treating a soln. of $[Cr_2(OH)(NH_3)_{10}]Cl_5.H_2O$ with an aq. soln. of chlorauric acid. It loses its water of crystallization at 100° ; and the salt is sparingly soluble in water. S. M. Jörgensen also prepared reddish-brown needles of **chromic trihydroxyaquohexamminochlorodichloraurate,** $[Cr(OH)_3(H_2O)(NH_3)_6]Cl(AuCl_4)_2$, from $[Cr_2(OH)_3(H_2O)(NH_3)_6]Cl_3.H_2O$, in an analogous manner. It loses a mol of water over sulphuric acid.

G. Neumann obtained **beryllium chromium pentachloride,** $BeCrCl_5.H_2O$, by the method used in connection with the analogous potassium salt. He prepared **magnesium chromium pentachloride,** $MgCrCl_5.H_2O$, in a similar way. S. M. Jörgensen prepared the complex **chromic hexamminotrichloromercurichloride,** $[Cr(NH_3)_6]Cl_3.HgCl_2$. According to O. T. Christensen, when a conc. aq. soln. of aquopentamminotrichloride is treated with mercuric chloride, yellowish-red, sparingly soluble **chromic aquopentamminotrichlorotrismercurichloride,** $[Cr(NH_3)_5(H_2O)]Cl_3(HgCl_2)_3.H_2O$, is formed. He also prepared yellowish-red needles of **chromic nitritopentamminodichlorobismercurichloride,** $[Cr(NH_3)_5(NO_2)]Cl_2(HgCl_2)_2$. S. M. Jörgensen similarly obtained **chromic chloropentamminodichlorotrismercurichloride,** $[Cr(NH_3)_5Cl]Cl_2(HgCl_2)_3$, in rose-red needles ; and P. T. Cleve, **chromic aquochlorotetramminodichlorotrismercurichloride,** $[Cr(NH_3)_4(H_2O)Cl]Cl_2(HgCl_2)_3$, in rose-red plates. G. Neumann prepared **thallous chromium hexachloride,** Tl_3CrCl_3, in hygroscopic, violet crystals, by the process used for potassium chromium pentachloride. R. F. Weinland and E. Gussmann prepared **chromic hexacetatohydroxyaquotripyridinochlorostannate,** $[Cr_3(CH_3COO)_6Py_3(H_2O)(HO)]SnCl_6.7H_2O$, in pale grey needle-like crystals, from the acetate of the series and sodium chlorostannate.

P. Pfeiffer and M. Tapuach prepared **chromic cis-dichlorobisethylenediaminochloroantimonate,** [Cr en_2Cl_2]$SbCl_6$, from the chloride of the series and a hydrochloric acid soln. of antimony pentachloride.

§ 26. Chromium Bromides and Oxybromides

A. Moberg[1] observed the formation of a dark green mixture when chromous chloride is treated with potassium bromide ; but the product was not examined. F. Wöhler, M. Bauck, and H. Moissan observed that **chromous bromide,** or **chromium dibromide,** $CrBr_2$, is formed by passing hydrogen over heated chromic bromide ; and H. Moissan also obtained it by the action of dry hydrogen bromide on chromium at a high temp. ; and by passing a mixture of bromine vapour and nitrogen over an excess of chromium at a red-heat. An aq. soln. of chromous bromide is formed by reducing a soln. of chromic bromide with zinc and hydrobromic acid. W. Biltz and E. Birk gave 4·356 for the sp. gr. at 25°/4°. According to A. Moberg, H. Moissan, F. Wöhler, and M. Bauck, white, crystalline chromous bromide readily fuses to a yellow liquid ; it forms a blue soln. with water, and the soln. quickly absorbs oxygen. The salt rapidly deliquesces in air forming green chromic bromide. The salt is soluble in alcohol. The presence of a trace of chromous bromide will bring anhydrous chromic chloride, bromide, or iodide into soln.—*vide supra*, chromic chloride. W. Biltz and E. Birk gave 1·714 for the sp. gr. of **chromous hexamminobromide,** $CrBr_2.6NH_3$, at 25°/4°. W. Traube and W. Passarge found that with hydrazine, chromous bromide forms **chromous dihydrazinobromide,** $CrBr_2.2N_2H_4$.

A. J. Balard obtained a soln. of **chromic bromide,** $CrBr_3$, by the action of bromine-water on the green hydrated chromic oxide, and the filtrate, when concentrated by evaporation, deposits green crystals—presumably the hydrate (*q.v.*). C. Löwig found that if lead chromate be boiled with hydrobromic acid, a dark green soln. is obtained ; he could not get the conc. soln. to crystallize, and he obtained a yellowish-red powder on evaporation. J. J. Berzelius used silver chromate in place of the lead salt. J. B. Berthemot obtained a soln. of the salt by the action of hydrobromic acid on chromic acid, in which case bromine is evolved ; he found that the green aq. soln. of chromic bromide turns brown on evaporation, and crystallizes with difficulty ; if further evaporated, the residue evolves hydrobromic acid. He prepared the anhydrous bromide by the action of bromine vapour on heated chromium—the combination is attended incandescence ; H. Moissan obtained it in an analogous way. F. Wöhler, and M. Bauck prepared it, as in the analogous case of chromic chloride, by the action of bromine vapour on a heated mixture of chromic oxide and carbon. F. Bourion prepared the bromide by passing the vapour of sulphur monochloride in a slow current of hydrogen bromide over chromic oxide at 135°, and finishing off with hydrogen bromide alone. The black plates or scaly crystals of chromic bromide appear olive-green by reflected light, and there is a pleochroic red colour as well. The powder is yellowish-green. W. Biltz and E. Birk gave 4·250 for the sp. gr. at 25°/4°. According to F. Wöhler, M. Bauck, and F. Bourion, when the anhydrous tribromide is heated in air, chromic oxide is formed ; in hydrogen, chromous bromide. The anhydrous salt appears to be insoluble in water, but it forms a green aq. soln. if a trace of chromous bromide be present. Chromic bromide deliquesces when exposed on tin-foil forming a green soln. The salt is soluble in boiling water ; alkali-lye decomposes it more easily than is the case with the chloride.

L. Varenne reported crystals of the *octohydrate*, $CrBr_3.8H_2O$, to be formed by treating a cold, conc. soln. of potassium or ammonium trichromate with dil. hydrobromic acid, and allowing the liquor to stand at 0°. The violet crystals are a combination of the cube and octahedron. The salt loses water at 110° and becomes green ; at 200°, in air, it forms an oxybromide, and finally chromic oxide. A. Werner and A. Gubser could not confirm these results. Chromic bromide furnishes a *hexahydrate* which occurs in two isomeric forms—green, and violet. The facts in connection with the isomeric hexahydrates of chromic chloride are applicable to the bromide. The **green hexahydrate** is considered to be **chromic dibromohexaquobromide,** $[(H_2O.Br)_2Cr(H_2O)_4]Br$, or $[Cr(H_2O)_4Br_2]Br.2H_2O$. A. Recoura obtained it by evaporating a sat. soln. of chromic oxide with a large excess of hydrobromic acid; and A. Werner and A. Gubser recommended passing hydrogen bromide over the evaporating soln. The green, hygroscopic crystals are acicular or tabular, which have, according to R. F. Weinland and A. Koch, the same optical properties as the green chloride, but it is rather stronger yellow tinge. A. Byk and H. Jaffe studied the violet and ultra-violet absorption spectrum of aq. soln. C. S. Garrett examined the effect of the chlorides of lithium, potassium, calcium, zinc, mercury, and aluminium on the mol. extinction of soln. of chromic bromide after standing 3 days, and 3½ months. The results are said to make it appear as if the water mols. play an initial part in changing the complex to the simple configuration, and that following this a second reaction sets in tending again to the formation of complexes owing to the presence of the colourless haloids in the soln. When, however, the colourless haloids have decidedly dehydrating properties, the hydration on dilution is initially inhibited, although the final point reached, when an excess of water mols. is present, is independent of the hygroscopic properties of the colourless haloid. N. Bjerrum found that the electrical conductivity of a freshly prepared soln. of a mol of the salt in 625 litres of water is 70 to 80 mhos at 0°, and 265·1 mhos at 25°. It forms only two ions, $[Cr(OH)_4Br_2]'$ and Br'. This is in agreement with the observation that only one-third of the bromine is at once precipitated on adding silver nitrate. E. Rosenbohm gave for the magnetic susceptibility, $13{\cdot}96\times10^{-6}$ mass units. A. Werner and A. Gubser found that the transformation of the green into the violet soln. is faster than is the case with the chloride. A. Recoura found that the salt is very soluble in water, and that the heat of soln. is 0·68 Cal. The aq. soln. reacts acid, and has a sweet taste. The salt is easily soluble in alcohol, and insoluble in ether. I. Koppel described a brown alcoholate, $CrBr_3.3C_2H_5OH$, or $[Cr(C_2H_5OH)_3Br_3]$, analogous to the red chloride; and P. Pfeiffer, the complex with pyridinium chloride, $[Cr(H_2O)_3Br_3].2PyHBr$. A. Werner and A. Gubser found that it is soluble in acetone, and precipitated by ether. N. Bjerrum said that it is soluble in fuming hydrobromic acid, but insoluble in a mixture of ether and this fuming acid. J. M. Ordway found that the aq. soln. of a mol of the salt dissolves 2 mols of the hydrated oxide.

The blue, greyish-blue, or **violet hexahydrate** is symbolized, as in the case of the corresponding hydrate of chromic chloride, by $[Cr(H_2O)_6]Br_3$, that is, **chromic hexaquotribromide.** A. Recoura prepared it by passing hydrogen bromide into a boiling, conc. soln. of the green hexahydrate. The soln. becomes brown, and as it cools, it deposits the violet salt. A. Werner and A. Gubser, and R. F. Weinland and A. Koch dissolved the product in a little water, and again passed hydrogen bromide into the soln. cooled below zero. G. O. Higley obtained the violet hexahydrate by saturating with hydrogen bromide a soln. of 5 grms. of the violet sulphate in 20 c.c. of water at 10°. The greyish-blue or violet powder was found by R. F. Weinland and A. Koch to have the same crystal form as the corresponding chloride. The violet and ultra-violet absorption spectra of the soln. were examined by A. Byk and H. Jaffe. The crystals are hygroscopic, and have a sweet taste. A. Recoura found that it dissolves in water with the development of 14·35 Cals. At 100°, it passes into the green isomer, and the heat of transformation from the green solid to the blue isomer is −2·17 Cals. The heat of the reaction $CrBr_{3\text{violet soln.}}+3NaOH_{\text{aq.}}=3NaCl_{\text{soln.}}+Cr(OH)_3$ is 21·6 Cals. The phenomena associated with the conversion of the green into the blue soln. resemble those in the analogous conversion with the chloride (*q.v.*). The rate of conversion is much greater with the bromide than with the chloride. Thus, the molar conductivity, μ mhos, of a $0{\cdot}008M$-soln., with time is:

1°	Time	0	2	8	25	70	110	160 min.
	μ .	76·7	77·2	94·5	111·1	125·8	136·3	156·1 mhos.
25°	Time	0	2	5	10	20	30	50 min.
	μ .	265·1	288·5	300·7	319·9	322·4	325·1	325·1 mhos.

The transformation to a state of equilibrium is thus completed in 30 min. at 25°, but not in 160 min. at 1°. A. Recoura gave 11·5 Cals. for the complete transformation of a mol of the green salt in soln. In the cold in dil. soln. the violet form is favoured, while an increase of temp., concentration, or the presence of hydrobromic acid favours the green. Unlike the case of the chlorides, N. Bjerrum found that the violet isomer occupies the greater vol. A. Recoura noticed that in concentrating a violet soln. of the bromide, the violet isomer first separates out, while with a violet soln. of the chloride, the dark green form appears. A. Werner and A. Gubser found the mol. conductivity of the violet soln. with a mol of the salt in v litres at 0° is $\mu=173$ mhos when $v=125$ at 0°, and at 25°, when $v=125$, 250, 500, and 1000, $\mu=329{\cdot}5$, 360·3, 391·2, and 431·6 mhos respectively. The results indicate that a mol. of the salt forms four ions when dissolved in water, *viz.*, $[Cr(H_2O)_6]^{\cdots}$ and $3Br'$, and is in agreement with the fact that all the bromine is at once precipitated by silver nitrate. The results are summarized by the formula $[Cr(H_2O)_6]Br_3$. A. Recoura said that the salt is insoluble in alcohol, A. Werner and A. Gubser said that it is soluble in acetone, and insoluble in ether. The hydrated chromic hydroxide precipitated by alkali-lye dissolves in acid forming the violet soln. E. Hein and co-workers studied some complexes with organic radicles.

S. M. Jörgensen[2] found that when a soln. of the hexamminonitrate is treated with conc. hydrobromic acid, and the precipitate is washed with dil. hydrobromic acid and then with alcohol, there is formed orange-yellow, rhombic plates of **chromic hexamminobromide,** $[Cr(NH_3)_6]Br_3$. F. Pintus also prepared this salt. W. Biltz and E. Birk found the sp. gr. to be 2·151 at 25°/4°, and the mol. vol. 183·2. J. Petersen, and P. Pfeiffer found the mol. wt. by the cryoscopic method and the mol. conductivity corresponds with the formation of four ions. H. J. S. King gave for the conductivity, μ mhos, of a mol of the salt in v litres at 25°, $\mu=355{\cdot}5$ for $v=64$; $\mu=391$ for $v=391{\cdot}1$; and $\mu=423{\cdot}3$ for $v=256$. It also forms a complex bromoplatinate. F. Ephraim and W. Ritter found that no ammonia is absorbed by the hexamminotribromide at room temp., but when cooled by a freezing mixture ammonia gas is absorbed, and the decomposition curve of the ammine of the hexamminotribromide is that represented by Fig. 78, and it shows that a triammine and monammine are formed. P. Pfeiffer, and F. Pintus obtained the corresponding **chromic trisethylenediaminotribromide,** $[Cr\,en_3]Br_3.nH_2O$; P. Pfeiffer and H. Pietsch, **chromic bisethylenediaminopropylenediaminotribromide,** $[Cr\,en_2pn]Br_3.3H_2O$; and F. Pintus, **chromium tripyridinotribromide,** $[CrPy_3]Br_3$. H. Farl studied the complexes with pyridine and chromic dichloroethylate. A. Benrath found that in the presence of hydrobromic acid, $[Cr(NH_3)_5Br]Br_2$, and $[Cr(NH_3)_5(H_2O)]Br_3$ are formed. O. T. Christensen prepared **chromic aquopentamminotribromide,** $[Cr(NH_3)_5(H_2O)]Br_3$, from an aq. soln. of the hydroxide and hydrobromic acid (1 : 3). The yellow crystalline powder is soluble in water, and loses a mol. of water at 110°. H. J. S. King also prepared this salt. F. Ephraim and W. Ritter found that the salt absorbs ammonia in the cold, and that the decomposition curve of the product shows the existence of an octammine and a tetrammine. A. Benrath found that the stable phase in the presence of hydrobromic acid is $[Cr(NH_3)_5Br]Br_2$. P. Pfeiffer treated chromic hydroxyaquotetramminodithionate with conc. hydrobromic acid, and obtained a brick-red crystalline powder of **chromic diaquotetramminotribromide,** $[Cr(NH_3)_4(H_2O)_2]Br_3$.

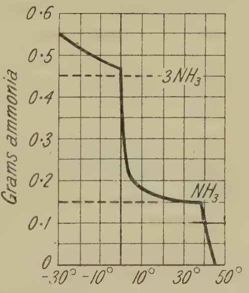

FIG. 78.—Dissociation of the Ammine of Chromic Hexamminotribromide.

P. Pfeiffer and R. Stern prepared **chromic cis-diaquobisethylenediaminotribromide,** $[Cr\,en_2(H_2O)_2]Br_3.2H_2O$; and P. Pfeiffer and R. Prade obtained the **trans-salt.** A. Werner prepared **chromic triaquotriamminotribromide,** $[Cr(H_2O)_3(NH_3)_3]Br_3$, by the action of hydrobromic acid on the hydroxyaquotriamminoiodide; and A. Werner and J. L. Klein, **chromic tetraquodiamminotribromide,** $[Cr(NH_3)_2(H_2O)_4]Br_3$, by the action of hydrobromic acid on the dihydroxydiaquodiamminobromide; P. Pfeiffer, and P. Pfeiffer and M. Tapuach also obtained **chromic tetraquodipyridinotribromide,** $[CrPy_2(H_2O)_4]Br_3.2H_2O$.

H. J. S. King prepared **chromic hydroxypentamminobromide,** $[Cr(NH_3)_5(OH)]Cl_2.\frac{1}{2}H_2O$, as in the case of the corresponding chloride. F. Ephraim and W. Ritter found that the salt absorbs ammonia in the cold but the decomposition curve shows no signs of the formation of a definite ammine. P. Pfeiffer prepared **chromic hydroxyaquotetramminodibromide,** $[Cr(NH_3)_4(H_2O)(HO)]Br_2$, by adding pyridine to a conc. soln. of the diaquotetramminodibromide. P. Pfeiffer, and P. Pfeiffer and R. Stern prepared **chromic cis-hydroxyaquobisethylenediaminodibromide,** $[Cr\,en_2(H_2O)(HO)]Br_2.H_2O$, or $[Cr\,en_2(H_4O_2)(HO)]Br_2$; and P. Pfeiffer and R. Prade prepared the **trans-salt.** O. T. Christensen obtained **chromic nitritopentamminodibromide,** $[Cr(NH_3)_5(NO_2)]Br_2$, by the action of potassium or ammonium bromide on the chloride of the series. S. M. Jörgensen obtained carmine-red octahedral crystals of **chromic chloropentamminodibromide,** $[Cr(NH_3)_5Cl]Br_2$, by the action of hydrobromic acid on the chloride of the series; he also obtained a complex with mercuric bromide. R. Klement gave 2·129 for the sp. gr., and 156·2 for the mol. vol. of the dibromide. S. M. Jörgensen, and P. T. Cleve prepared **chromic chloroaquotetramminodibromide,** $[Cr(NH_3)_4(H_2O)Cl]Br_2$, by the action of hydrobromic acid on the chloride of the series. R. Werner and A. Miolati found the electrical conductivity of a mol of the salt in *v* litres of water at 25° to be :

v	125	250	500	1000	2000
μ	220·7	236·8	251·1	264·8	290·9

S. M. Jörgensen, and O. T. Christensen prepared **chromic bromopentamminodibromide,** $[Cr(NH_3)_5Br]Br_2$, by the action of hydrobromic acid on the product of the action of silver oxide on the chloropentamminodichloride. R. Klement gave 2·382 for the sp. gr., and 158·2 for the mol. vol. It forms a complex chloroplatinate. The nitrate, chloride, and chromate of the series $Cr(NH_3)_5BrX_2$ were also obtained. F. Ephraim and W. Ritter found that the salt absorbs no ammonia. A. Benrath found that the salt is stable in the presence of hydrobromic acid. R. Klement gave 1·961 for the sp. gr. and 146·9 for the mol. vol. of **chromic bromopentamminodichloride,** $[Cr(NH_3)_5Br]Cl_2$. H. Freundlich and R. Bartels studied the hydrolysis of the salt $[Cr(NH_3)_5Br]^{\cdot\cdot}+H_2O=Br'+[Cr(NH_3)_5(H_2O)]^{\cdot\cdot\cdot}$. P. T. Cleve, and P. Pfeiffer and S. Basci prepared **chromic bromoaquotetramminodibromide,** $[Cr(NH_3)_4(H_2O)Br]Br_2$, by the action of hydrobromic acid on an ammoniacal soln. of ammonium bromide and chromic hydroxide. The chloride and sulphate of the series were also prepared. A. Werner obtained **chromic bromodiaquotriamminodichloride,** $[Cr(NH_3)_3(H_2O)_2Br]Cl_2$; and also **chromic bromodiaquotriamminodibromide,** $[Cr(NH_3)_3(H_2O)_2Br]Br_2$; as well as the corresponding sulphate. P. Pfeiffer and R. Stern, and P. Pfeiffer and T. G. Lando obtained **chromic bromoaquobisethylenediaminodibromide,** $[Cr\,en_2(H_2O)Br]Br_2.H_2O$. A. Werner and J. von Halban prepared dark orange crystals of **chromic thiocyanatopentamminodibromide,** $[Cr(NH_3)_5(SCy)]Br_2$; H. I. Schlesinger and D. N. Rickles also prepared **chromium cis-dibromotetramminochloride,** $[Cr(NH_3)_4Br_2]Cl$, by the action of boiling hydrobromic acid on **chromium triamminochloroxalate,** $[Cr(NH_3)_3Cl(C_2O_4)]$. They also prepared the corresponding **chromium cis-dibromotetramminobromide,** $[Cr(NH_3)_4Br_2]Br$, **chromium cis-dibromotetramminoiodide,** $[Cr(NH_3)_4Br_2]I$, etc. They also prepared **chromium trans-dibromotetramminobromide,** $[Co(NH_3)_3Br_2]Br$, by the action of hot hydrobromic acid on chromium triamminobromide. A. Werner and J. L. Klein obtained lilac-coloured crystals of **chromic dihydroxydiaquodiamminobromide,** $[Cr(NH_3)_2(H_2O)_2(OH)_2]Br.H_2O$, by the action of pyridine on a soln. of dibromodiaquodiamminobromide; and E. Weinmann, on chromic dihydroxydiaquoethylenediaminoiodide, $[Cr(H_2O)_2\ en(OH)_2]I$. P. Pfeiffer and W. Osann prepared **chromic dihydroxydiaquodipyridinobromide,** $[CrPy_2(H_2O)_2(OH)_2]Br$. P. Pfeiffer and T. G. Lando, and A. Werner prepared **chromic cis-dichlorobisethylenediaminobromide,** $[Cr\ en_2Cl_2]Br.H_2O$, A. Werner, and P. Pfeiffer and P. Koch obtained the **trans-salt;** P. Pfeiffer and M. Tapuach, **chromic dichlorodiaquodipyridinobromide,** $[CrPy_2(H_2O)_2Cl_2]Br.3H_2O$; P. Pfeiffer and A. Trieschmann, **chromic cis-dibromobisethylenediaminobromide,** $[Cr\ en_2Br_2]Br.H_2O$, as well as the corresponding iodide, and dithionate. The **trans-salt** was also obtained as well as the corresponding iodide, nitrate, iodide, and thiocyanate. E. H. Riesenfeld and F. Seemann, and S. Guralsky prepared **chromic dibromoaquotriamminobromide,** $[Cr(NH_3)_3(H_2O)Br_2]Br$, as well as the corresponding iodide, sulphate, nitrate, and thiocyanate. Y. Shibata measured the absorption spectrum of the bromide. N. Bjerrum found that **chromic dibromotetraquochloride,** $[Cr(H_2O)_4Br_2]Cl.2H_2O$, is precipitated when a cold soln. of chromic dibromotetraquobromide in dil. hydrochloric acid is sat. with hydrogen chloride. Its constitution is deduced from its method of formation, its colour, which resembles that of the dibromobromide, and from the ease with which the halogen in the metallic complex is brought into the ionized state by soln. in water or nitric acid. He also prepared **chromic dichlorotetraquobromide,** $[Cr(H_2O)_4Cl_2]Br$, in a similar manner, as an unstable, green, crystalline powder; titration by silver nitrate shows that only one halogen atom is in the ionized state in soln. A. Werner and J. V. Dubsky, and A. Werner and J. L. Klein prepared **chromic dibromodiaquodiamminobromide,** $[Cr(NH_3)_2(H_2O)_2Br_2]Br$; and P. Pfeiffer and M. Tapuach, **chromic dibromodiaquodipyridinobromide,** $[CrPy_2(H_2O)_2Br_2]Br.4H_2O$, as well as the corresponding nitrate, and iodide. P. Pfeiffer and M. Tilgner obtained **chromic dithiocyanatotetramminobromide,** $[Cr(NH_3)_4(SCy)_2]Br$; P. Pfeiffer and P. Koch, **chromic dithiocyanatobisethylenediaminobromide,** $[Cr\ en_2(SCy)_2]Br.H_2O$, and P. Pfeiffer obtained the trans-salt; P. Pfeiffer, **chromic oxalatotetramminobromide,** $[Cr(NH_4)_4(C_2O_4)]Br.\frac{1}{2}H_2O$; H. Schwarz, P. Pfeiffer and A. Trieschmann, **chromic oxalatobisethylenediaminobromide,** $[Cr\ en_2(C_2O_4)]Br.H_2O$.

H. I. Schlesinger and D. N. Rickles prepared **chromic triamminotribromide,** $[Cr(NH_3)_3Br_3]$, **chromic triamminochlorodibromide,** $[Cr(NH_3)_3Br_2Cl]$, and **chromic triamminodichlorobromide,** $[Cr(NH_3)_3BrCl_2]$, as in the case of chromic triamminotrichloride, by the thermal decomposition of the corresponding pentammines at 175°. The corresponding iodo-, nitrato-, and nitrito-salts could not be similarly obtained.

S. M. Jörgensen, J. Petersen, and P. Pfeiffer prepared **chromium hydroxydecamminopentabromide,** $[Cr_2(OH)(NH_3)_{10}]Br_5.H_2O$, and its bromoplatinate; as well as **chromic hydroxydecamminohydroxytetrabromide,** $[Cr_2(OH)(NH_3)_{10}]Br_4(OH).H_2O$. S. M. Jörgensen described **chromic hydroxydecamminotetrabromide,** $[Cr_2(OH)(NH_3)_{10}]Br_4.2H_2O$; P. Pfeiffer and R. Stern, **chromic dihydroxybisethylenediaminotetrabromide,** $[Cr(OH)_2en_2]Br_4.2\frac{1}{2}H_2O$; S. M. Jörgensen, **chromic trihydroxyaquohexamminotribromide,** $[Cr_4(OH)_3(H_2O)(NH_3)_6]Br_3.H_2O$; P. Pfeiffer and W. Vorster, **chromic hexaquosexiesethylenediaminohexabromide,** $[Cr_4(OH)\ en_6]Br_6.4H_2O$.

A. Werner and A. Gubser prepared **rubidium chromium bromide,** $2RbBr.CrBr_3.H_2O$, or $Rb[CrBr_5(H_2O)]$, from a soln. of 3 grms. of rubidium bromide, 8 grms. of green chromic bromide, and 10 grms. of water. The brownish-violet crystals are soluble in water. S. M. Jörgensen prepared **chromic chloropentamminodibromomercuribromide,** $[Cr(NH_3)_5Cl]Br_2.2\frac{1}{4}HgBr_2$; and P. Pfeiffer, **chromic dibromobisethylenediaminobromomercuribromide,** $[Cr\ en_2Br_2]Br.HgBr_2$.

H. Rose[3] heated a mixture of potassium dichromate and bromide with sulphuric acid, and found that bromine distils over without a trace of chromium. No signs of a **chromyl bromide,** CrO_2Br_2, analogous with the corresponding chloride was obtained. S. G. Rawson also failed to prepare the compound by H. Rose's method, and also by heating calcium bromide and chromyl chloride in sealed tubes at varying temp. and varying periods of time. H. S. Fry found that a soln. of acetyl bromide in carbon tetrachloride, to which a few drops of acetic acid are added, produces an intense permanganate-red coloration, which rapidly changes to reddish-brown. The latter colour is due to bromine, and the former to an unstable chromyl bromide. The production of the permanganate-red colour is recommended as a test for traces of chromium, and is capable of detecting 0·01 mg. per 1 c.c. of solvent.

A. Ditte prepared **potassium bromochromate,** $KCrO_3Br$, from a mixed soln. of chromic acid and potassium bromide evaporated in the cold in vacuo. J. Heintze obtained it from a soln. of potassium chromate and fuming hydrobromic acid. The red crystals lose bromine in the desiccator ; water decomposes the salt into potassium dichromate and hydrobromic acid ; and with nitrogen peroxide, nitroxyl bromide is formed.
